The new program, apart from the exact filter algorithm, now also features a novel 3D deconvolution algorithm based on the idea that one can predict the 3D point-spread function (PSF) for any 3D reconstruction geometry. The correct 3D reconstruction is then calculated by the 3D deconvolution of the unfiltered 3D reconstruction with the PSF. This 3D deconvolution algorithm scales proportionally to the number of projections used to generate a 3D reconstruction (the exact filter algorithm scales as the *square* of the number of projections) and yields results of the same overall quality as the classical exact filter algorithm (Harauz & van Heel, 1986).

19.9.10. Angular reconstitution 4D refinements

With the angular reconstitution approach (van Heel, 1987; van Heel *et al.*, 2000) one typically assigns a Euler angle orientation to a 2D image by finding its best overall sinogram correlation peaks with respect to an 'anchor set' of 2D projections from one single 3D structure. The *IMAGIC* 'Euler' program, which performs the angular reconstitution orientational search, has now been extended to loop over multiple anchor sets and has thus been upgraded to a 4D level. As a consequence, the Euler program is now capable of competitively choosing the best anchor set among anchor sets generated from different 3D structures. The program can thus now also be used for refining towards multiple 3D structures, as was already the case with the MRA program in *IMAGIC*.

19.9.11. Discussion

The potential benefits of 4D cryo-EM at atomic resolution are obvious. With some further developments, 4D cryo-EM may become the structural-biology method *par excellence*. The growing importance of software in cryo-EM has been the subject of various editorials and special issues of journals (Carragher & Smith, 1996; Smith & Carragher, 2008). The processing of 4D data sets, however, requires solving a large set of 3D structures simultaneously and that is necessarily a complex matter. The researcher will have to understand the basic principles of the approach and its pitfalls, and will thus have to go through a steep learning curve. The basic methodology (and the use of *IMAGIC*) is taught in courses such as the EMBO course for 3D cryo-EM, or the Brazil school for single-particle cryo-EM (www.single-particles.org/school/). The *IMAGIC 4D* system is aimed at accompanying the user at the appropriate level of complexity, without forcing the user to become an expert script programmer. Throughout the *IMAGIC 4D* system, the software will directly understand the 4D frame of thinking of the user.

There is a growing understanding in the field that continuity of development, maintenance and support of the software for cryo-EM is an important issue for the success of a project. One needs to safeguard the human investment in mastering the learning curve, and one needs continuity of support over the duration of a (long-term) project. Software continuity is at least as important as it is to continue maintaining electron microscopes for data collection in cryo-EM. An example of a successful community effort to consolidate software instrumentation in the field of X-ray crystallography is the maintenance of the *CCP4* suite of programs (Collaborative Computational Project, Number 4, 1994). One must realize, however, that this model cannot be transferred directly to the cryo-EM field because each of the handful of packages in use in single-particle cryo-EM is at least as complex as the *CCP4* system, largely due to the necessity of parallelization.

One further remark about using scripts for running existing software: scripts tend to lead a life of their own and are often exchanged among users; combinations of scripts are sometimes even distributed as a 'new' package. However, scripts are operating-system dependent, and any change in the original programs requires updating of all associated scripts in all different operating systems. The lack of 'backward' compatibility with existing scripts actually impedes the development of the original software, since many users may refuse to update the core software to avoid having to modify their (borrowed) scripts. Creating wrappers (Python) to interface with original programs has a similar effect of possibly hampering software evolution.

Another compatibility issue is that of the formats used in cryo-EM. The original 2D stack format of *IMAGIC* (van Heel & Keegstra, 1981) is one of the richest formats in use in cryo-EM and therefore it is possible to convert from all file formats in use in cryo-EM into *IMAGIC* without loss of information. The popular *EM2EM* conversion program (www.imagescience.de) for converting all cryo-EM formats into each other is an *IMAGIC* program that converts formats without any unnecessary loss of header data. The popular *CCP4* volume data format (Collaborative Computational Project, Number 4, 1994) has been adopted as a standard for the current EM databases (Smith & Carragher, 2008). This format is a 3D format, with one header record for the full 3D volume. It can also hold a single 2D image, but it cannot hold a stack of images, each with its own header record, as is required for single-particle cryo-EM. For 4D cryo-EM applications a 4D format will be required for the structure databases. There is some urgency for the cryo-EM and X-ray communities to agree on a more elaborate common density format for our structure databases.

Atomic resolution structures (~3 Å) have hitherto been elucidated mainly by X-ray crystallography, where the biological molecules are confined to the rigidity of a 3D crystal. Single-particle cryo-EM gives a direct window into the solution, revealing a plethora of different views, of different complexes, in different functional states, albeit at a resolution level still somewhat inferior to that achieved by X-ray crystallography and NMR spectroscopy. Single-particle cryo-EM techniques are now approaching resolution levels previously only achievable by X-ray crystallography. For a better understanding of biological processes, it is essential to see the sequence of conformational changes and interactions that molecules undergo during their functional cycle. A primary challenge in structural biology today is to generate '4D movies' of biological complexes at (quasi)-atomic resolution. The new *IMAGIC 4D* software has been tailored for such 4D analysis at atomic resolution.

We acknowledge recent financial support from the EU/NOE (grant No. NOE-PE0748), from the Dutch Ministry of Economic Affairs (Cyttron project No. BIBCR_PX0948) and from the BBSRC (grant No. BB/G015236/1). We thank all users of the *IMAGIC* system for constructive feedback and past contributors for their code and ideas. We also acknowledge the use of the *Eclipse/SVN* software suite for helping to keep the *IMAGIC* system coherent with contributors operating from three different continents.

Chapter 19.10. Single-particle reconstruction with *EMAN*

S. Ludtke

19.10.1. Introduction

Single-particle reconstruction is a technique for determining the three-dimensional structure of identical nanoscale objects without requiring crystallization (Frank, 2006). Typical targets are large proteins or macromolecular assemblies, with ~200 kDa regarded as the lower size limit for this technique due to high image noise levels. Typical non-viral targets are in the size range from 500 kDa to 5 MDa, with icosahedral viruses extending to hundreds of megadaltons. Several examples of structures being reconstructed to ~4 Å resolution using this technique have been published (Ludtke *et al.*, 2008; Jiang *et al.*, 2008; Zhang *et al.*, 2008; Yu *et al.*, 2008) and subnanometre resolution is frequently achieved, but in negative stain, or with unusually difficult specimens, resolutions may still be limited to 12–30 Å.

19.10.2. Overview of *EMAN*

EMAN is a suite of scientific image-processing tools with a particular focus on cryogenic electron microscopy (cryo-EM) and single-particle reconstruction. The first stable version was released in 1999 and it has undergone continuous development since that time. Since roughly 2005, development has focused on *EMAN2*, with a completely redesigned modular image-processing library, a workflow system, and a new openGL-based graphical user interface (GUI). *EMAN2* supports virtually all image file formats used in the cryo-EM community, as well as various conventions for particle-orientation specification. The image-processing library is completely modular, so new algorithms can be made available throughout the system without any modification of end-user programs. Metadata, which refer to both experimental and derived information describing the image data, are archived using an embedded database system. These metadata can be harvested to produce information for manuscripts or for deposition to centralized databases such as the EMDB (http://www.emdatabank.org), operated by the PDBe (Europe) and RCSB PDB (USA).

EMAN2 has a tiered structure. The GUI interface and workflow represent the top of the hierarchy. Next are individual command-line programs, providing the user with a greater level of control and a wide range of utility functions. Below this is the Python (http://www.python.org) layer, for interactive use or high-level programming. Finally, we have the C++ core image-processing library, which handles all computationally intensive image processing. Full documentation is provided through the *EMAN* wiki (http://blake.bcm.tmc.edu/eman/eman2).

19.10.2.1. GUI layer and workflow

The workflow interface (Fig. 19.10.2.1) is designed to guide the end user through entire processes, while storing a complete record of all processing completed during any given task. While this interface is gradually being expanded with new tasks, such as tomographic particle averaging, for the purposes of this discussion we will focus on the single-particle reconstruction task, which is broken down into a number of discrete subtasks as discussed in detail in Section 19.10.3. The workflow is designed so that users wishing to perform only a subset of any task can easily import data into any subtask, proceed through additional subtasks, then export the results at any point. There are future plans to integrate other cryoEM software into the workflow interface to enable users to try alternative algorithms for specific subtasks. The workflow is accessed using either `e2workflow.py` or `e2desktop.py`.

The GUI interface (Fig. 19.10.2.2) includes a number of visualization modules for displaying individual two-dimensional images, stacks of two-dimensional images, three-dimensional volumetric models, two-dimensional plots, three-dimensional plots and symmetry information. These modules are used by the interactive file/database browser available in the workflow or *via* the program `e2display.py`, but may also be used directly from the Python interface.

19.10.2.2. Command-line programs

EMAN2 (Tang *et al.*, 2007) currently contains ~60 command-line programs for specific tasks, plus an additional ~60 programs as part of the related *SPARX* project (Hohn *et al.*, 2007), included with *EMAN2* releases. High-level programs such as `e2refine2d.py`, `e2initialmodel.py`, `e2eotest.py` and `e2refine.py` are essentially wrapper scripts which call the lower-level Python scripts to complete specific tasks.

In addition, there are a number of general-purpose utility programs, such as `e2proc2d.py` for two-dimensional image processing, `e2proc3d.py` for three-dimensional image processing and `e2bdb.py` for access to the embedded database. Both `e2proc2d.py` and `e2proc3d.py` take similar arguments and

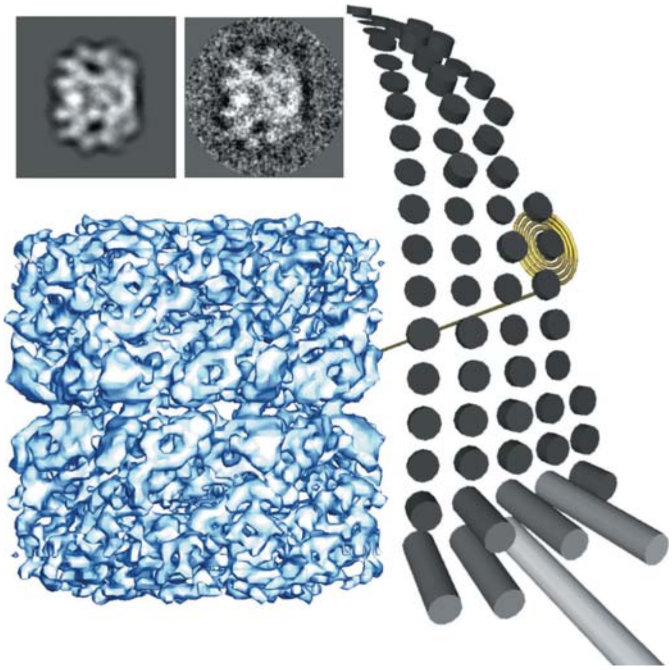

Figure 19.10.2.2
A representation of the Euler GUI tool. The three-dimensional reconstruction is shown (lower left), along with a projection and class average for a particular orientation identified in the asymmetric triangle on the right. Each cylinder in the asymmetric triangle represents a projection direction, with its height representing the number of particles found in that orientation.

permit application of any of the ~170 modular image-processing algorithms in the core library *via* the `--process` option. These include filters, masks, mathematical operations and a range of other processing algorithms. The `e2help.py` program provides detailed documentation for all of the modular algorithms. All *EMAN2* programs are able to read automatically any of the supported file formats, and will write to any supported file format based on file extension or explicit specification of output format. For example, the command to convert a three-dimensional volume from HDF format to MRC format is simply `e2proc3d.py input.hdf output.mrc`.

19.10.2.3. Python wrapper

Python is an easy-to-learn scripting language in wide use in both scientific and non-scientific disciplines. It provides both an interactive prompt as well as a programming interface, and is easily extensible using higher-performance languages such as C++. *EMAN2* was designed such that all command-line programs and the entire GUI interface are written in Python. Thus, any of the distributed programs in *EMAN2* can be modified by experienced end users without a full *EMAN2* compilation environment. In addition, the program `e2.py` offers an *iPython*-based (http://ipython.scipy.org) interactive prompt which gives full access to all of the library functions and GUI tools of *EMAN2*. An introduction to this interface can be found at http://blake.bcm.edu/emanwiki/Eman2ProgQuickstart.

19.10.2.4. C++

The C++ interface contains a modular system, so algorithms of various types can be trivially made available to the entire workflow system. The C++ and Python interfaces were intentionally designed to be as similar to each other as possible, so prototypes of new algorithms can be developed in Python and then later ported to C++. See http://blake.bcm.edu/emanwiki/Eman2CProgQuickstart for an introduction.

Table 19.10.2.1
Listing of *EMAN2* supported file formats and whether each has read (R) and/or write (W) support

BDB refers to the *EMAN2* embedded database. DM2/3 are Gatan Digital Micrograph formats. LST files are text files from *EMAN1*.

Format	R or W support	Format	R or W support
BDB	R/W	TIFF	R/W
HDF5	R/W	PGM	R/W
MRC	R/W	PNG	R/W
IMAGIC	R/W	JPEG	W
SPIDER	R/W	LST	R/W
PIF	R/W	*AMIRA*	R/W
DM3	R	*XPLOR*	W
DM2	R	VTK	W
EM	R/W	*FITS*	R/W
ICOS	R/W	SAL	R

19.10.2.5. Cross-platform support

All of the major computing platforms are supported, including Linux workstations and clusters, Mac OSX and Windows. Our primary development platforms are Linux and OSX. While we are committed to full support of *EMAN2* on Windows, we have encountered idiosyncratic behaviour on some specific machines running Vista which have defied explanation, but we continue to strive for full support.

19.10.2.6. Parallel processing

The three-dimensional refinement process can be extremely computationally intensive. While a refinement of a small ~1 MDa particle with some symmetry to 15 Å resolution may be accomplished on a single workstation in a few hours, a project like an asymmetric reconstruction to 4 Å resolution could easily require hundreds of thousands of CPU hours. Updated details of the modular parallelism strategy of *EMAN* and its GPGPU (general purpose graphics processing unit) methodology can be found in the wiki at http://blake.bcm.edu/emanwiki/EMAN2/Parallel.

19.10.2.7. File formats and other conventions

EMAN2 supports all cryo-EM file formats for which specifications were available, in addition to its embedded database storage mechanism. While any *EMAN2* program can read and write images in any supported format, we have adopted HDF5 as an interchange format and the internal database BDB for use during workflow operations. These two permit arbitrary metadata to be associated with each image, unlike the standard cryo-EM formats. Table 19.10.2.1 contains a list of the currently supported formats.

The other primary convention of concern to single-particle reconstruction is three-dimensional orientation specification. While *EMAN2* has its own convention, it can convert to and from the most common conventions in use in the cryo-EM community, including *MRC*, *SPIDER*, *IMAGIC*, quaternions and spin axis. *EMAN*'s own convention uses Z-X-Z' Euler angles named az, alt and phi, respectively.

19.10.3. Single-particle reconstruction

The single-particle reconstruction process is broken down into a sequence of subtasks in the *EMAN2* workflow. Each subtask is documented in the GUI, with a block of text and mouse-over popups. While the workflow is the method of choice for performing reconstructions, all of the individual subtasks can also be completed using direct command-line programs. The workflow is launched with the `e2workflow.py` program. For each stage, the alternative command-line program is also shown in parentheses.

19.10.3.1. Particle selection (`e2boxer.py`)

Locating images of individual particles in the micrograph/charge-coupled device (CCD) frame is arguably the most critical and labour-intensive step in single-particle processing. Owing to the high noise levels in typical cryo-EM images, combined with various types of contamination, correctly identifying all relevant particles within a micrograph is challenging (Zhu *et al.*, 2004). Despite many years of effort, no reliable and generally applicable algorithms for fully automated particle picking exist. The present approach of *EMAN2* is to streamline the process of semi-automated particle picking. Multiple CCD frames/micrographs can be opened simultaneously and are handled by the user as a group. At the time of writing, there is a single autopicking algorithm available, based on Woolford *et al.* (2007), but there are plans to expand this in the future.

19.10.3.2. Contrast transfer function/image evaluation (`e2ctf.py`)

EMAN1 contained a very accurate contrast transfer function (CTF) correction methodology, which was also very labour-intensive. While the mathematical basis for correction remains effectively unchanged, the correction methodology is now entirely automatic. The only substantial change to the mathematical formulation is that the spectroscopic profile of the background noise, which was originally characterized using four empirical parameters, is now specified as a data-derived non-parametric curve. In addition, this methodology permits the computation of a one-dimensional structure factor from sets of images without user intervention, a process which was quite challenging in *EMAN1* (Ludtke *et al.*, 1999). The automated process is supplemented by a fully featured GUI for manual image assessment.

19.10.3.3. Grouping particles into sets

Once images have been preprocessed, the user is given another, optional, opportunity to examine the images of individual particles, now in Wiener-filtered form, to identify any 'bad' particles which should be eliminated from further processing. In addition, several values are provided to the user which permit assessment of particles on a per-micrograph basis, such as the integrated signal-to-noise ratio, defocus and B factor. Particles from user-selected micrographs are then combined into a set for further processing.

19.10.3.4. Reference-free two-dimensional classification (`e2refine2d.py`)

This fully automated principal-component-analysis-based (Frank, 2006) process produces two-dimensional averages representative of the various particle views present in the raw images. As with the workflow as a whole, while the user can provide a large number of different options for this subtask, sensible default values are provided, which should produce good results in most cases. The two-dimensional classification process is quite similar to the corresponding process in *EMAN1* (Chen *et al.*, 2006), with subtle improvements to increase speed and accuracy.

The two-dimensional classification process generates class averages with improved signal-to-noise, characteristic of the different orientations and dynamic states of the particles. These can be used to help identify the particle's symmetry and any problems with preferred orientation or particle flexibility/heterogeneity.

19.10.3.5. Initial model generation (`e2initialmodel.py`)

There are a variety of opinions in the single-particle reconstruction community about how initial models should be generated. Briefly, the most widely used methods are: common lines with reference-free class averages (van Heel, 1987), random conical tilt (Radermacher *et al.*, 1987), orthogonal tilt (Leschziner & Nogales, 2006) and single-particle tomography with three-dimensional averaging (Walz *et al.*, 1997). While not the primary method we promote for traditional single-particle processing, the *EMAN2* workflow includes a task for three-dimensional alignment and averaging of tomographic subvolumes.

The primary method provided to generate initial models in *EMAN2* is based on the robustness of the iterative refinement strategy used for the final high-resolution refinement (Section 19.10.3.6). For any given three-dimensional structure, there are a small number of stable structures which can result from refinement, regardless of starting model. The correct model represents the global minimum in the energy space defined by requiring that projections of the reconstruction match the particle images.

To make use of this concept in *EMAN2*, we downsample the two-dimensional class averages (Section 19.10.3.4) and make a large number of completely random starting models, then quickly iteratively refine each. While the speedups used in this process make it more susceptible to local minima than the full high-resolution refinement method, it will generally still produce the correct model some fraction of the time, without having to resort to additional experiments. The resulting models are easily assessed by comparing the original class averages with projections of the model, so the best answer can be readily identified. The primary risk associated with this process is with respect to particles with structural heterogeneity in solution or those with strongly preferred orientations, in which case the standard refinement algorithm is not robust. In such cases, the tomographic method can provide further insights.

19.10.3.6. Refinement (`e2refine.py`)

Once particles have been prepared and an initial model has been produced, the next step is three-dimensional refinement. This process is largely unchanged from *EMAN1* (Ludtke *et al.*, 1999), apart from minor improvements designed to speed up the process and provide additional flexibility. As with two-dimensional refinement, there are a large number of options for the user to specify, but, where possible, sensible defaults are provided. Documentation for the various parameters is provided through the workflow interface.

19.10.4. Evaluating the reconstruction

Evaluating the final three-dimensional reconstruction remains one of the most problematic aspects of single-particle processing from a quantitative standpoint, and there have been numerous debates in the community over standards for model assessment. As the field is now beginning to achieve resolutions where protein side chains can be visualized, reliable new assessments based on methods from X-ray crystallography are emerging, but at lower resolutions robust assessment remains elusive.

19.10.4.1. Model accuracy

Before assessing the resolution of a reconstruction, the fundamental question of whether the model even qualitatively represents the original data must be addressed. Regardless of the reconstruction methodology used, the fundamental questions to be asked are whether computed projections of the reconstruction match both the raw particles and class averages, and whether all of the particle views are represented by the three-dimensional model in some orientation. The 'Eulers' option in the workflow provides a number of tools for making such model assessments both qualitatively and quantitatively.

19.10.4.2. Measures of resolution and resolvability

Resolution in single-particle processing is distinct from the related concept of resolvability. Resolvability is a measure of the level of detail visible in a model, in terms of the shortest separation distance over which two objects can be identified as being distinct. However, in structural biology, 'resolution' is a statement of the spatial frequency at which the noise level exceeds a threshold. It is important to recognize that a model with 4 Å resolution could be low-pass filtered to a resolvability of only 20 Å, and yet cryo-EM resolution measures would still (properly) show it to have 4 Å resolution. To help bring the resolvability in line with the resolution, it is typical to apply an appropriate filter to the three-dimensional reconstruction such that the resolvability is in reasonable agreement with the resolution, but there remains no consensus in the community over the optimal filter and/or filtration level appropriate for this task. *EMAN2* provides a signal-to-noise-ratio- and structure-factor-based technique, as well as two mechanisms for assessing the resolution of a reconstruction.

19.10.4.3. Model/noise bias

The final issue to consider in a single-particle reconstruction is the well known model/noise bias problem (Stewart & Grigorieff, 2004). With a traditional iterative refinement strategy, and very high noise levels in the raw particle images, it is possible to produce a reconstruction including features derived from the initial model or from systematic algorithmic artifacts which are not represented in the raw data. There are relatively few techniques for assessing this sort of bias, and each single-particle reconstruction package handles this issue differently. In *EMAN*, the use of iterative class averaging during the iterative refinement process permits this bias to be greatly reduced or eliminated, when used as suggested. Ensuring that the reference-free class averages agree well with projections of the reconstruction can at least place some limits on the extent of such artifacts.

The development of *EMAN2* is funded by NIH grant No. R01GM080139. I would like to thank David Woolford for his work on the figures, and Ben Bammes and Jesus Montoya for their comments.

PART 20. ENERGY CALCULATIONS AND MOLECULAR DYNAMICS

Chapter 20.1. Molecular-dynamics simulation of protein crystals: convergence of molecular properties of ubiquitin

U. Stocker and W. F. van Gunsteren

20.1.1. Introduction

Molecules in crystals are often believed to have a very rigid structure due to their ordered packing, and the investigation of the molecular motion of such systems is often considered to be of little interest. In contrast to small-molecule crystals, however, the solvent concentration in protein crystals is high, usually with about half of the crystal consisting of water. Thus, in this respect, one can compare protein crystals with very concentrated solutions and expect non-negligible atomic motion. The atomic mobility in proteins can be investigated by experiment (X-ray diffraction, NMR) or by molecular simulation.

Today's experimental techniques are very advanced. They are, however, only able to examine time- and ensemble-averaged structures and properties. In contrast, with simulations one can go beyond averaged properties and examine the motions of a single molecule in the pico- and nanosecond time regime. Such simulations have become possible with the availability of high-resolution structural data, which provide adequate starting structures for biologically relevant systems. Depending on the kind of property in which one is interested, different methods of simulation may be used. Equilibrium properties can be obtained using either Monte Carlo (MC) or molecular-dynamics (MD) simulation techniques, but motions can only be observed with the latter. Current interest in the simulation community mainly focuses on dissolved proteins as they would be in their natural environment. Force fields are parameterized to mimic the behaviour and function of proteins in a solution, and few crystal simulations have been performed. Consequently, a crystal environment provides an excellent opportunity to test a force field on a task for which it should be appropriate, but for which it has not been directly parameterized.

Apart from the analysis of the dynamic properties of a system, MD simulations are also used in structure refinement. In refinement, be it X-ray crystallographic or NMR, a special term is added to the standard physical force field to reflect the presence of experimental data:

$$V(\mathbf{r}) = V^{\rm phys}(\mathbf{r}) + V^{\rm special}(\mathbf{r}). \qquad (20.1.1.1)$$

In NMR, a variety of properties can be measured, and each of these can be used in the definition of an additional term that restrains the generated structures to reproduce given experimental values. Refinement procedures exist that use nuclear-Overhauser-effect (van Gunsteren *et al.*, 1984; Kaptein *et al.*, 1985), *J*-value (Torda *et al.*, 1993) and chemical-shift (Harvey & van Gunsteren, 1993) restraints. In crystallography, X-ray intensities are used to generate the restraining energy contribution (Brünger *et al.*, 1987; Fujinaga *et al.*, 1989). Combined NMR/X-ray refinement uses both solution and crystal data (Schiffer *et al.*, 1994).

As in an experiment, averages over time and molecules are measured, and instantaneous restraints can lead to artificial rigidity in the molecular system (Torda *et al.*, 1990). This can be circumvented by restraining time or ensemble averages, instead of instantaneous values, to the value of the measured quantity. Time averaging has been applied to nuclear Overhauser effects (Torda *et al.*, 1990) and *J* values (Torda *et al.*, 1993) in NMR structure determination and to X-ray intensities in crystallography (Gros *et al.*, 1990; Gros & van Gunsteren, 1993; Schiffer *et al.*, 1995). Ensemble averaging has been applied in NMR refinement (Scheek *et al.*, 1991; Fennen *et al.*, 1995). For a more detailed discussion of restrained MD simulations, we refer to the literature (van Gunsteren *et al.*, 1994, 1997).

The first unrestrained MD simulations of a protein in a crystal were carried out in the early 1980s (van Gunsteren & Karplus, 1981, 1982). The protein concerned was bovine pancreatic trypsin inhibitor (BPTI), a small (58-residue) protein for which high-resolution X-ray diffraction data were available. The initial level of simulation was to neglect solvent, using vacuum boundary conditions. This was improved gradually by the inclusion of Lennard–Jones particles at the density of water as a solvent (van Gunsteren & Karplus, 1982) to let the protein feel random forces and friction from the outside as well as feel a slightly attractive external field. The next step was to use a simple (simple point charge, SPC) water model (van Gunsteren *et al.*, 1983). Further improvement was achieved by incorporating counter ions into the modelled systems to obtain overall charge neutrality (Berendsen *et al.*, 1986).

Despite these early attempts, few unrestrained crystal simulations have been reported in the literature, and, to our knowledge, these involve one to four protein molecules, simulating one unit cell (Shi *et al.*, 1988; Heiner *et al.*, 1992). The maximum time range covered has been less than 100 ps.

In the work described in this chapter, the current state of MD simulation of protein crystals is illustrated. A full unit cell of ubiquitin, containing four ubiquitin and 692 water molecules, has been simulated for a period of two nanoseconds. Since this simulation is an order of magnitude longer than crystal simulations in the literature, it offers the possibility of analysing the convergence of different properties as a function of time and as a function of the number of protein molecules. Converged properties can also be compared with experimental values as a test of the *GROMOS*96 force field (van Gunsteren *et al.*, 1996). Finally, the motions obtained can be analysed to obtain a picture of the molecular behaviour of ubiquitin in a crystalline environment.

20.1.2. Methods

Ubiquitin consists of 76 amino acids with 602 non-hydrogen atoms. Hydrogen atoms attached to aliphatic carbon atoms are incorporated into these (the united-atom approach), and the

Copyright © 2012 International Union of Crystallography

remaining 159 hydrogen atoms are treated explicitly. Ubiquitin crystallizes in the orthorhombic space group $P2_12_12_1$, with a = 5.084, b = 4.277 and c = 2.895 nm. There is one molecule in the asymmetric unit. The protein was crystallized at pH 5.6. The amino acids Glu and Asp were taken to be deprotonated, and Lys, Arg and His residues were protonated, leading to a charge of +1 electron charge per chain. Because this is a small value compared with the size of the system, no counter ions were added. Four chains of ubiquitin, making up a full unit cell of the crystal, were simulated together with 692 water molecules modelled using the SPC water model (Berendsen *et al.*, 1981). 232 water molecules were placed at crystallographically observed water sites, and the remaining 460 were added to obtain the experimental density of 1.35 g cm^{-3}, leading to a system size of 3044 protein atoms and 5120 atoms total.

The crystal structure of ubiquitin [Protein Data Bank (Bernstein *et al.*, 1977) code 1UBQ] solved at 1.8 Å resolution (Vijay-Kumar *et al.*, 1987) was used as a starting point. To achieve the appropriate total density, noncrystallographic water molecules were added, using a minimum distance of 0.220605 nm between non-hydrogen protein atoms or crystallographic water oxygen atoms and the oxygen atoms of the added water molecules, which were taken from an equilibrated water configuration (van Gunsteren *et al.*, 1996). Initial velocities were assigned from a Maxwell–Boltzmann distribution at 300 K. The protein and solvent were coupled separately to temperature baths of 300 K with a coupling time of 0.1 ps (Berendsen *et al.*, 1984). No pressure coupling was applied. Another simulation (results not shown) including pressure coupling showed no significant change in the box volume. Bonds were kept rigid using the *SHAKE* method (Ryckaert *et al.*, 1977), with a relative geometric tolerance of 10^{-4}. Long-range forces were treated using twin range cutoff radii of 0.8 and 1.4 nm (van Gunsteren & Berendsen, 1990). The pair list for non-bonded interactions was updated every 10 fs. No reaction field correction was applied. All simulations were performed using the *GROMOS*96 package and force field (van Gunsteren *et al.*, 1996).

The system was initially minimized for 20 cycles using the steepest-descent method. The protein atoms were harmonically restrained (van Gunsteren *et al.*, 1996) to their initial positions with a force constant of 25000 kJ mol^{-1} nm^{-2}. This minimized structure was then pre-equilibrated in several short MD runs of 500 steps of 0.002 ps each, gradually lowering the restraining force constant from 25000 kJ mol^{-1} nm^{-2} to zero. The time origin was then set to zero, and the entire unit cell was simulated for 2 ns. The time step was 0.002 ps, and every 500th configuration was stored for evaluation. The first 400 ps of the run were treated as equilibration time, the remaining 1.6 ns were used for analysis.

20.1.3. Results

20.1.3.1. Energetic properties

In Fig. 20.1.3.1, the non-bonded contributions to the total potential energy are shown. The non-bonded interactions comprise Lennard–Jones and electrostatic interactions. Solvent–solvent, solute–solute and solute–solvent interaction energies are shown separately. All of these appear converged after approximately 100 ps. The solvent–solvent energy remains close to its initial value during the whole simulation, the water molecules having relaxed during the pre-equilibration period, while the protein was restrained. The protein internal energy increases during the first few hundred picoseconds, but this is compensated by a decrease in the protein–solvent energy as the protein adapts to the force field and the pre-relaxed solvent environment. This effect becomes negligible after about 200 ps, from which time point the system can be viewed as equilibrated with respect to the energies. The distribution of kinetic *versus* potential energy and the total (bonded and non-bonded) energy of the system relaxes even faster (results not shown).

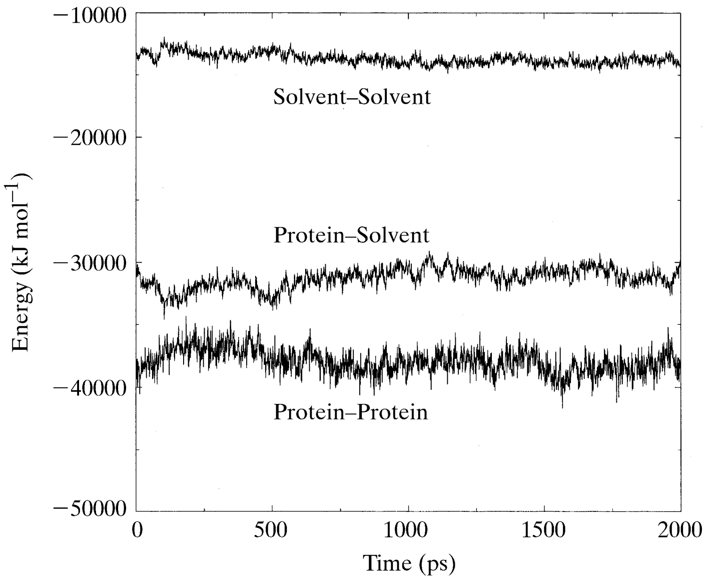

Figure 20.1.3.1
Non-bonded energies (in kJ mol^{-1}) of the simulated system as a function of time.

20.1.3.2. Structural properties

Not all properties converge as fast as the energies. Fig. 20.1.3.2 shows the root-mean-square atom-position deviation (RMSD) from the X-ray structure for each of the four individual chains for both Cα atoms and all atoms. Here, several relaxation periods can be distinguished. After the initial increase, which occurs during the first 50 ps of the simulation, a plateau is reached, and the

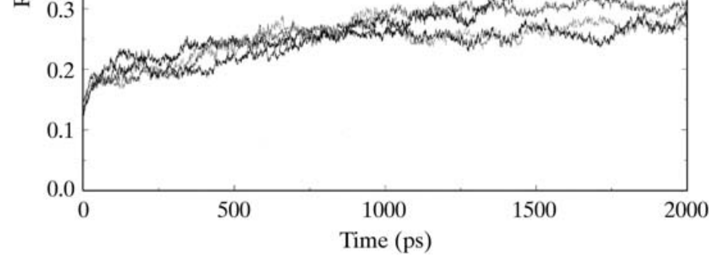

Figure 20.1.3.2
Root-mean-square atom-positional deviations (RMSD) in nm from the X-ray structure of the four different protein molecules in the unit cell as a function of time. Rotational and translational fitting was applied using the Cα atoms of residues 1–72. The upper and lower graphs show the deviations for the Cα atoms and for all atoms, respectively.

system is apparently stable until 300 ps. The values reached are 0.12 nm for the Cα atoms and 0.20 nm if all atoms are considered. These numbers are comparable with results obtained in crystal simulations of other proteins of equivalent length reported in the literature (van Gunsteren *et al.*, 1983; Berendsen *et al.*, 1986; Shi *et al.*, 1988; Heiner *et al.*, 1992; Levitt *et al.*, 1995). After 300 ps, however, the values increase slowly again. For the Cα atoms, there is apparently a second plateau from 300 to 850 ps, but during this period the RMSD for all atoms continues to increase monotonically. After 850 ps, a final plateau is reached. During the second nanosecond of the simulation (1000–2000 ps), the RMSDs are 0.21 nm for the Cα atoms and 0.29 nm for all atoms. The RMSD of chain 1 is an exception. There is a strong increase after 1200 ps due to a movement of a particular part of the chain which will be addressed later. To ensure that the RMSD values have converged, longer runs would be required.

Although the RMSD values shown in Fig. 20.1.3.2 grow larger than those usually observed in the course of short simulations, the hydrogen-bonding pattern and thus the secondary-structure elements observed in the X-ray structure are reproduced well (Table 20.1.3.1). Most of the hydrogen bonds reported (Vijay-Kumar *et al.*, 1987) show high occupancies during the whole simulation, especially the ones within secondary-structure elements. Only six out of the 44 hydrogen bonds present in the X-ray structure are disrupted during the simulation. Hydrogen bonds in the α-helix (residues 23–34) show very high occupancies, ranging from 75% at the N-terminus to well over 90% inside the helix. Only its C-terminus shows signs of instability, with the α-helix deforming towards a 3_{10}-helix. The β-sheet pattern is, apart from chain 1 in the region of residues 49–64, as stable as the α-helix. Occupancies range from 55% up to 95%. The six hydrogen bonds not reproduced (five 3_{10} and one α-helical) can be rationalized as follows. The bridges 10–7 and 65–62 are part of the most mobile regions of the protein. These regions involve residues 7–10, 51–54 and 62–65 (Vijay-Kumar *et al.*, 1987). The hydrogen bond at the C-terminal end of the α-helix (35–31) is lost, and the preceding hydrogen bond (34–30) is partly changed, indicating that the end of the α-helix is deformed towards a 3_{10}-helix. The donor of the bond 40–37 is replaced by residue 41, and the four-residue 3_{10}-helix that was stabilized by hydrogen bonds 58–55 and 59–56 is replaced by an α-helical hydrogen bond 59–55. The high occupancy of this particular bond and the complete absence of the two observed experimentally indicate an early rearrangement in this part of the structure (before the analysis period) which is stable during the rest of the simulation.

Backbone–side-chain hydrogen bonds are less well reproduced than backbone–backbone interactions. While some are present 80–90% of the time, others are present less than 50% of the time. Two out of the seven hydrogen bonds in which a backbone atom is the donor are not observed in the simulation; both involve the OG1 atom of Thr7 as an acceptor. The hydrogen-donor atoms are the backbone nitrogen atoms of residues Thr9 and Lys11, both of which have high experimental *B* factors (18.32 Å^2 for Thr9 and 13.56 Å^2 for Lys11). The mean of the experimental *B* factors is 10.73 Å^2 for the backbone atoms and 13.41 Å^2 for all protein atoms. Where a side-chain atom is the donor, three out of the five hydrogen bonds present in the X-ray structure are not found in the simulation. All of these involve the side-chain nitrogen atom of a lysine residue as the donor, the experimental *B* factors of which range from 23.92 Å^2 for the NZ atom of Lys48 up to 30.06 Å^2 for the NZ atom of Lys33. Of the four side-chain–side-chain hydrogen bonds, not one is observed as in the crystal. The 54–58 hydrogen bond is, however, replaced by a 55–58 hydrogen bond. All the others involve very mobile atoms with large experimental *B* factors as donors and acceptors.

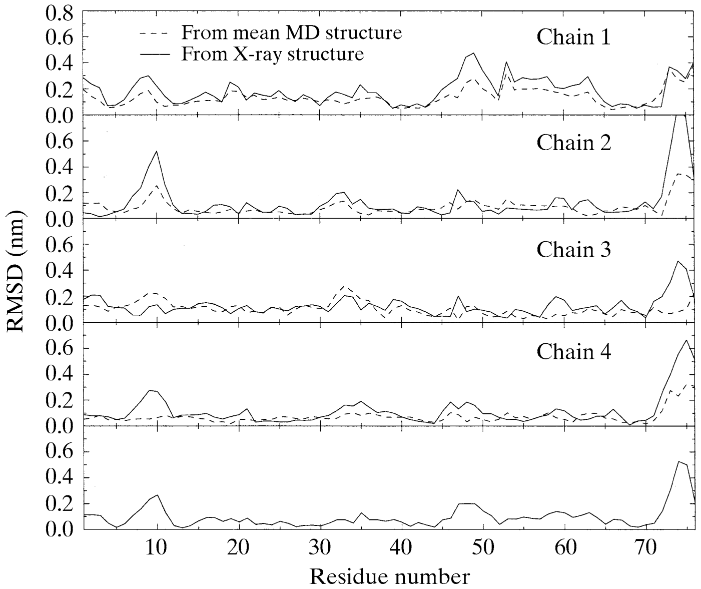

Figure 20.1.3.3
Root-mean-square Cα-atom-position deviation (RMSD) in nm from a reference structure as a function of the residue number using the final 1.6 ns of the simulation. RMSDs of the four protein molecules in the unit cell from the mean molecular-dynamics structure (dashed line) and from the X-ray structure (solid line) are shown in the first four graphs. The bottom graph shows the RMSD of the mean (over the four molecules) MD structure from the X-ray structure.

There is one intermolecular hydrogen bond (Table 20.1.3.2) in the starting structure which is not seen in the simulation. The donor is the side-chain nitrogen atom of Lys6, which has an experimental *B* factor of 20.55 Å^2, and the acceptors are the side-chain oxygen atoms of Glu51, with *B* factors of 32.13 and 33.44 Å^2. Most of the hydrogen bonds not reproduced in the simulation contain at least one mobile atom. Although these atoms do not remain fixed at their equilibrium positions, they may still stabilize the structure on average.

In Fig. 20.1.3.3, the deviation of the Cα atoms of the different chains from the X-ray structure and from the mean MD structure are presented together with the deviation of the mean MD structure from the X-ray structure. Overall, the individual protein molecules remain close to the experimental structure; however, parts of the structure do deviate substantially. The region involving residues 7–11, which experimentally has high *B* factors (implying high mobility), has, in three out of the four cases, an RMSD for Cα atoms of 0.3 nm or greater. Chain 3, in contrast, is close to the X-ray structure, and the mean MD structure is closer to the X-ray structure than are any of the individual chains. This suggests that the simulation does not deviate systematically from the X-ray structure, but rather that different regions of conformational space are sampled by the different molecules. The same holds for the very mobile region between residues 47 and 64, where chain 1 deviates dramatically from both the mean MD structure and the X-ray structure. In the other chains, this part of the protein remains close to the X-ray structure. Overall, the deviation from the X-ray structure is largest in the C-terminal region. This part is also ill-defined in the experiment, with occupancies of 0.45 for residues 73 and 74, and 0.25 for the terminal two glycines. Other parts of the protein, especially the stable secondary-structure elements, stay close to the X-ray structure. In the average structure, the α-helix, including its C-terminal part which was deformed to a 3_{10}-helix, deviates by a

Table 20.1.3.1

Occurrence of intramolecular hydrogen bonds (%) during the final 1.6 ns of the simulation

The criteria for a hydrogen bond to be present are angle donor–hydrogen–acceptor ≥ 135°, distance hydrogen–acceptor ≤ 0.25 nm. Hydrogen bonds are shown if they are either present in the X-ray structure or if at least one of the four protein molecules in the unit cell shows the hydrogen bond of interest for at least 50% of the simulation time. The letter h appended to an amino-acid code indicates that the residue is protonated.

maximum of 0.08 nm from the X-ray structure, although, as seen before, the individual chains may deviate more. The β-sheet regions also stay close to the X-ray structure. As with the helix, residues 1–7, 40–45 and 64–72 stay within 0.1 nm RMSD from the X-ray structure. The β-strands formed by residues 10–17 and 48–50 are not as similar to the experiment, since they lie close to mobile regions and are thus influenced by neighbouring mobile residues. For the strand formed by residues 10–17, from residue 12 onwards the same structural similarity is reached as for all other secondary-structure elements, and residues 48–50 are, again, strongly influenced by the moving part of chain 1.

20.1.3.3. Effect of the translational and rotational fitting procedure

In Fig. 20.1.3.4, the impact of different fitting protocols on atomic mean-square position fluctuations (RMSFs) is examined. B factors are related to mean-square position fluctuations according to

$$B_i = (8\pi^2/3)\big\langle(\mathbf{r}_i - \langle\mathbf{r}_i\rangle)^2\big\rangle, \qquad (20.1.3.1)$$

where the angle brackets indicate a time or a combined time and ensemble average. Molecule 4 was selected because it is the most stable. RMSFs of the Cα atoms were calculated directly from the simulation trajectory (Fig. 20.1.3.4*a*) after applying a translational fit using the Cα atoms of residues 1–72, which are well defined in the X-ray structure (Fig. 20.1.3.4*b*), and after applying both a rotational and a translational fit on residues 1–72 (Fig. 20.1.3.4*c*). In Fig. 20.1.3.4(*d*), a translational and rotational fit was applied to all Cα atoms (residues 1–76). Removal of the overall translational component of motion reduces the positional fluctuations by 0.04 nm on average. Only the RMSFs in the proximity of the

end of the large α-helix formed by residues 23–34 are not affected by the introduction of translational fitting. In contrast, it is exactly this region where the fluctuations are substantially lowered by introducing an additional rotational fit. The regions before residue 27 and after residue 42 are only slightly affected by the removal of overall rotation. These findings suggest that the entire protein translates by about 0.04 nm, while the α-helix region remains close to its initial position, thus rotating relative to the rest of the protein. Inclusion of the four C-terminal residues in the fitting procedure only affects the RMSFs of these residues and residues in the rotating part of the molecule, indicating that these four residues move together with the rest of the molecule. The atom-position fluctuations obtained by applying a full (rotational and translational) fit are determined by internal motion only. The largest RMSFs for residues 1–72 are 0.12 nm. RMSFs of the two C-terminal glycines are 0.26 nm if the last four residues are excluded from the fitting and 0.22 nm otherwise.

If the same properties are examined but averaged over all the chains, similar trends can be observed (Fig. 20.1.3.5). If no fitting is applied, the RMSFs of 0.24 nm, on average, indicate that the different molecules show relative translation and rotation. After translational fitting is applied, the mean RMSFs drop to 0.18 nm. Thus, the molecules translate within the unit cell. If, in addition, the rotational component of overall motion is removed, the whole helix region is much less mobile than before, and the mean RMSFs drop to 0.14 nm. The same holds for region 47–64, dominated by the rotation of part of chain 1. Fluctuations are generally much larger than before when only chain 4 was observed, again indicating that the distinct chains behave in an uncorrelated way. The size of the peaks of the RMSFs averaged over all chains is around 0.22 nm, compared with 0.27 nm when overall rotation is still present. Thus, in addition to internal rotations, relative rotations of the different molecules occur. If the fit is not applied only to the well defined Cα atoms of residues 1–72, the RMSF value becomes slightly higher – apart from the C-terminal region – but this effect is small, with the mean RMSF staying at 0.14 nm. However, the relative heights of the peaks differ, which shows that it is crucial to define a standard fitting

Table 20.1.3.2
Occurrence of intermolecular hydrogen bonds (%) during the final 1.6 ns of the simulation

The criteria for a hydrogen bond to be present are: angle donor–hydrogen–acceptor $\geq 135^\circ$, distance hydrogen–acceptor ≤ 0.25 nm. Hydrogen bonds are shown if they are either present in the X-ray structure or if at least one of the four protein molecules in the unit cell shows the hydrogen bond of interest for at least 50% of the simulation time.

Hydrogen bond		X-ray structure	Molecular dynamics			
			Molecules 1–4	Molecules 2–3	Molecules 3–2	Molecules 4–1
6 Lys HZ3	51 Glu OE1	100	0	0	0	0
12 Thr HG1	18 Glu OE1	0	56	57	75	34
49 Gln H	8 Leu O	0	10	34	0	67
68 Hish HE2	32 Asp OD2	0	0	0	53 (3–1)	13 (4–2)
71 Leu H	58 Asp O	0	65	0	0	0

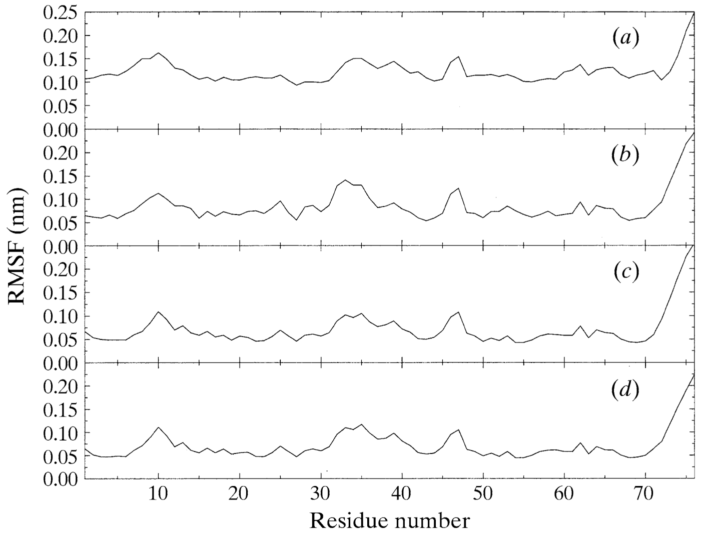

Figure 20.1.3.4
Root-mean-square Cα-atom-position fluctuations (RMSFs) in nm are shown for molecule 4 as a function of residue number. RMSFs are averaged over the final 1.6 ns. In (*a*), no fitting was applied; in (*b*), translational fitting was applied using the Cα atoms of residues 1–72; and in (*c*), the rotational component of motion was also removed. In (*d*), translational and rotational fitting was applied over all Cα atoms (1–76).

protocol that must not be changed during the course of the analysis.

20.1.3.4. Effect of the averaging period

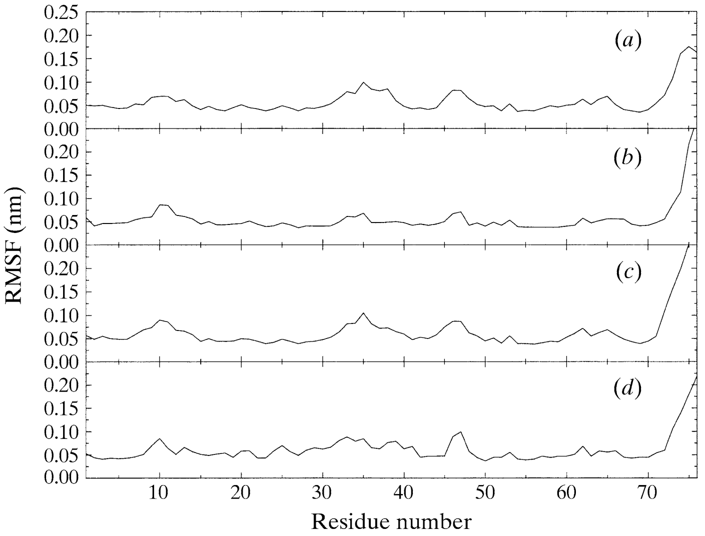

Figure 20.1.3.6
Root-mean-square Cα-atom-position fluctuations (RMSFs) in nm are shown for molecule 4, with full translational and rotational fitting over the Cα atoms of residues 1–72. Different averaging periods are compared. (*a*) shows the RMSFs for the period 400–800 ps, (*b*) shows those for the period 800–1200 ps. In (*c*), the results for the previous two periods are averaged (400–1200 ps), and in (*d*), the results for the period 1200–2000 ps are shown.

In Fig. 20.1.3.6, we concentrate again on molecule 4. Comparing different averaging periods of 400 and 800 ps with different starting points, it can be seen that, in general, the later the simulation, the less motion observed. During the period 800–1200 ps, only the small region between residues 9 and 12 shows more mobility than that between 400 and 800 ps. In the stable region, the rest of the molecule shows the same mobility as in the earlier time period. In the parts that are most mobile between 400 and 800 ps, the motions decrease significantly after the latter time point, indicating that equilibrium is reached. Focusing on the longer averaging periods, 400–1200 ps *versus* 1200–2000 ps, we see that over the whole chain mobility is comparable, indicating clear equilibrium as far as internal motions are concerned. The fluctuations during the 400–1200 ps period are of the same size as those of the shorter subperiods, 400–800 ps and 800–1200 ps. They are thus determined by movements on a timescale shorter than 400 ps.

In Fig. 20.1.3.7, the effect of different averaging periods is again considered, but taking the whole unit cell into account. Comparing RMSFs between 400 and 800 ps with those of the following 400 ps period, no significant difference is seen. In fact, contrary to what was observed when chain 4 was examined, somewhat more mobility is evident in the later period compared with the earlier one. This difference shows that although the configurations of the single chains converge rapidly, the different chains visit different parts of phase space. The fact that the fluctuations in the period 400–1200 ps are between those of the two shorter analysis periods is another indication that the single-

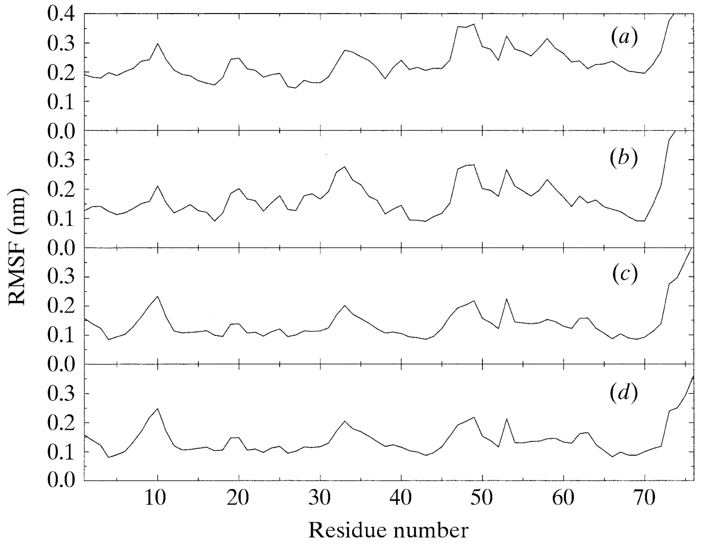

Figure 20.1.3.5
Root-mean-square Cα-atom-position fluctuations (RMSFs) in nm are shown using the same fitting protocols as in Fig. 20.1.3.4, but averaged over all four protein molecules in the unit cell.

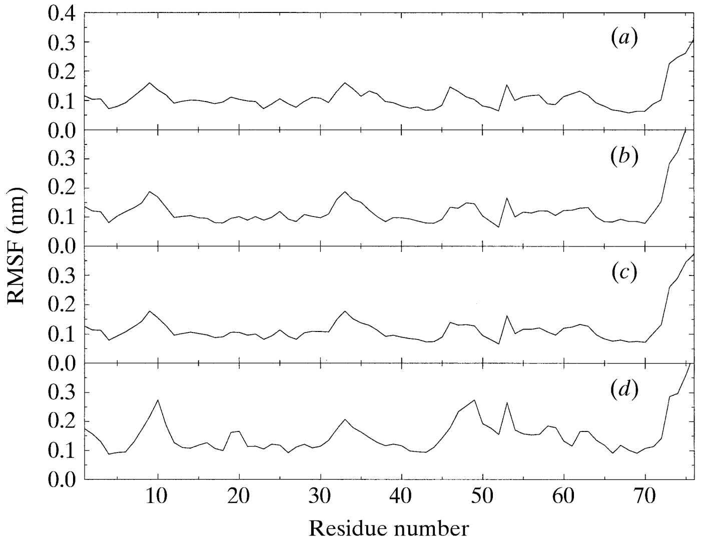

Figure 20.1.3.7
Root-mean-square Cα-atom-position fluctuations (RMSFs) in nm are shown using the same averaging periods as in Fig. 20.1.3.6, but averaged over all four protein molecules in the unit cell.

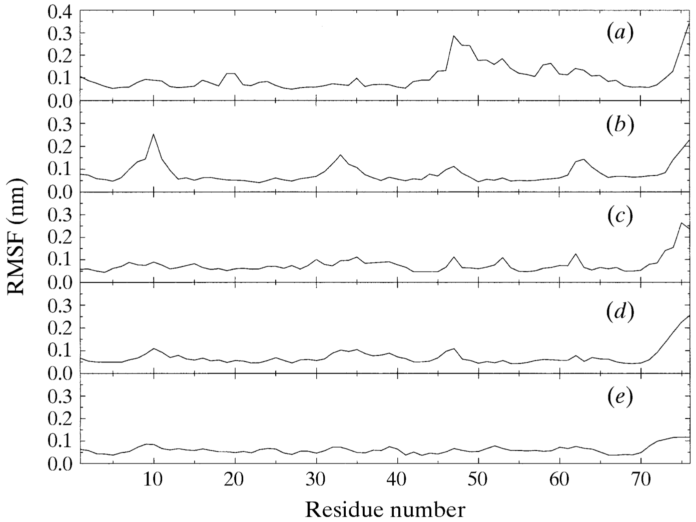

Figure 20.1.3.8

Root-mean-square Cα-atom-position fluctuations (RMSFs) in nm for the four protein molecules in the unit cell as a function of the residue number. Full translational and rotational fitting was applied to the Cα atoms of residues 1–72 using the final 1.6 ns of the simulation [(*a*)–(*d*)]. (*e*) shows the corresponding values defined by equation (20.1.3.1), obtained from experimental *B* factors.

chain movements are converged on these short timescales. In the last 800 ps of the simulation, the RMSFs are substantially higher than in the 800 ps window before that. All of the peaks can be traced back to one of the single chains. If only one of the four molecules differs strongly from the other three, this one determines the magnitude of the fluctuations of the average. The peak at residue 10 comes from chain 2, the ones around residue 20 and the whole region 47–64 are determined by chain 1. The peak at residue 33 originates in chain 3, which at this point differs substantially from the mean MD structure (Fig. 20.1.3.3).

20.1.3.5. Internal motions of the proteins

Fig. 20.1.3.8 displays the atomic root-mean-square position fluctuations for the Cα atoms of the four protein molecules during the whole analysis period, together with corresponding values obtained using equation (20.1.3.1) and the crystallographic *B* factors. Rotational and translational fitting was applied using the Cα atoms of residues 1–72, and the fluctuations were averaged over the final 1.6 ns. The mobility of the stable secondary-structure elements in the simulation is comparable with that inferred from the experiment. There is a correlation between the more mobile parts of the proteins in the simulation and large *B* factors in the X-ray structure, but the magnitude of the fluctuations is overestimated in the simulation. The movements of the single chains can be rationalized as follows. In chain 1, the whole region from Gly47 onwards rotates around a stable axis formed by residues 41–46. This part lies, as do all the flexible regions, on the exterior of the protein. Residues 19 and 20, which are stable in all but this single chain, are in contact with this moving part. This rotation, which tends to compact the protein, occurs during the 200 ps period between 1350 and 1550 ps after the start of the simulation, in which the atom-position RMSD from the X-ray structure increases significantly (Fig. 20.1.3.2). Overall, chain 2 is more stable than chain 1. Nevertheless, the end of the unwinding helix shows large fluctuations. In the course of this deformation, the side-chain nitrogen atom of Lys11 moves from close to the OE atom of Glu34 towards the backbone oxygen atom of Lys33, which is associated with a change in the position of Gly10. A similar but smaller motion occurs in chain 4. Both lysines, Lys33 and Lys63, are fully exposed to the solvent and have no intramolecular contacts. In chain 3, the flexible residues are also not part of secondary-structure elements and are located on the outside of the protein. The backbone oxygen atom of Gln62 that moves in all the four chains has, in addition, the closest contact to another heavy atom: the OG1 atom of Ser65 is only 2.51 Å away, and the van der Waals repulsion of these atoms causes them to move further away from one another. The mobile residues in chain 4 are again in contact with the solvent, Gly35, Gly47, Gln62, the end of the helix and Gly10. The terminal residues of all the protein molecules are very mobile, as observed experimentally in the crystal.

Table 20.1.3.3

Root-mean-square fluctuations of polypeptide backbone and ψ dihedral angles (°) for the different molecules using different time-averaging periods

The bottom row shows the averages over all four protein molecules.

Molecule	400–800 ps φ/ψ	400–1200 ps φ/ψ	400–2000 ps φ/ψ
1	18.4/22.9	19.5/23.7	31.0/33.6
2	17.2/17.0	18.6/18.7	23.6/26.8
3	18.5/20.4	25.6/26.3	35.3/37.5
4	19.7/18.8	19.4/20.3	21.6/28.8
All	26.1/26.2	28.0/28.6	35.2/38.1

20.1.3.6. Dihedral-angle fluctuations and transitions

Backbone dihedral-angle fluctuations and transitions are examined in Tables 20.1.3.3 and 20.1.3.4 using different analysis periods. After the first 400 ps of analysis, the φ/ψ dihedral-angle fluctuations differ only slightly, but if longer averaging times are chosen, the different protein molecules show larger differences

Table 20.1.3.4

Number of protein-backbone dihedral-angle transitions per 100 ps for the different molecules using different time periods

Dihedral angles with threefold and sixfold potential-energy wells are distinguished. The bottom rows show the averages over all protein molecules.

(*a*) 120° transitions

Molecule	400–800 ps	400–1200 ps	400–2000 ps
1	46.5	45.4	47.7
2	40.5	41.5	47.3
3	50.5	57.1	51.3
4	44.8	46.4	46.4
All	45.6	47.6	48.2

(*b*) 60° transitions

Molecule	400–800 ps	400–1200 ps	400–2000 ps
1	245.5	246.6	289.3
2	271.5	272.1	261.3
3	381.5	381.0	348.3
4	356.8	325.4	325.4
All	313.8	306.3	306.1

(*c*) All transitions

Molecule	400–800 ps	400–1200 ps	400–2000 ps
1	292.0	292.0	336.9
2	312.0	313.7	308.6
3	432.0	438.1	399.6
4	401.5	371.8	371.8
All	359.4	353.9	354.2

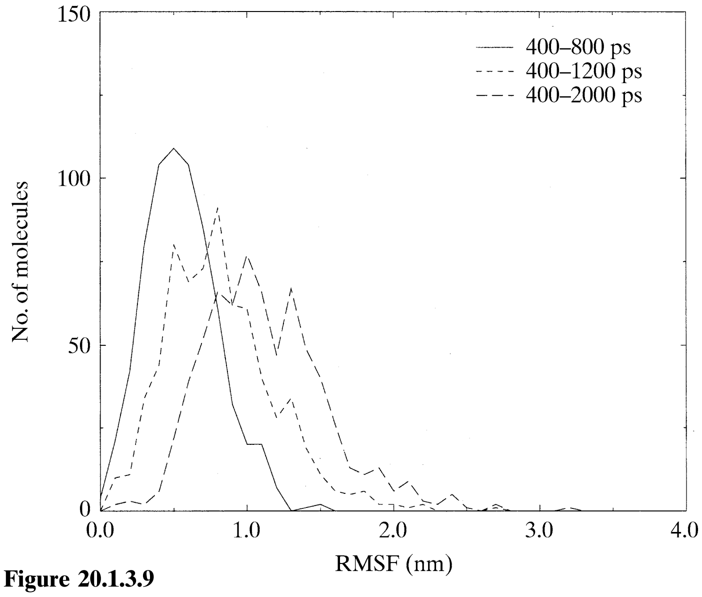

Figure 20.1.3.9
The number of water molecules with a given root-mean-square oxygen-position fluctuation (RMSF) in nm are shown for different averaging periods: 400–800 ps (solid line), 400–1200 ps (short-dashed line), 400–2000 ps (long-dashed line).

from one another. These fluctuations also increase for longer analysis times, indicating that they are not yet converged after 2 ns. In the period from 800 to 1200 ps, chain 3 shows a large increase in mean-square dihedral-angle fluctuations, whereas the Cα-atom-position RMSDs with respect to the X-ray structure during the same time fluctuate around a plateau. Thus, there is a lot of flexibility without the simulation structure diverging from the experimental one. Protein molecule 3, for example, shows the largest φ/ψ fluctuations of all the four molecules, and it shows the lowest atom-position RMSDs of Cα atoms from the X-ray structure at the end of the simulation (Fig. 20.1.3.2), indicating that it explores phase space around the equilibrium structure. If, in contrast, the Cα-atom-position RMSDs, with respect to the X-ray structure, increase significantly, larger dihedral-angle fluctuations are also observed, for example, in molecule 1 after 1200 ps.

Concerning relaxation, observations similar to those made before can be made when analysing dihedral-angle transitions (Table 20.1.3.4). The number of transitions for the different chains differs by about 20%. Within a single chain, however, the number of transitions increases in proportion to the observation time. Again, the protein molecules showing the most transitions do not have the largest Cα-atom-position RMSDs from the X-ray structure. Thus, only certain dihedral-angle flips induce large movements that determine the RMSD value.

20.1.3.7. Water diffusion

In Fig. 20.1.3.9, the number of water oxygen atoms with a given atomic root-mean-square position fluctuation (RMSF) are plotted. The time evolution and the shapes of these curves are similar to those obtained for bulk water, a Gaussian distribution with the maximum at larger RMSF values and larger standard deviations when using longer averaging times. Using a diffusion constant of bulk SPC water at 300 K of 3.9×10^{-3} nm^2 ps^{-1} (Smith & van Gunsteren, 1995), the root-mean-square position fluctuation for an average water molecule would be 1.25 nm for a 400 ps period, 1.77 nm for a 800 ps period, and 2.5 nm for a 1600 ps period. Comparison of these values with the distributions in Fig. 20.1.3.9 indicates that the motion of most of the crystal water molecules is restricted by the crystalline environment. A number of water molecules adopt well defined positions for periods of the order of some 100 ps. Several water molecules were also observed to visit the same location repeatedly. This indicates that, although not remaining fixed in space, they stay close to a crystallographically determined site which they revisit periodically, alternating with other water molecules.

20.1.4. Conclusions

In the present molecular-dynamics simulation, fast convergence in energy, within about 100 ps, was observed. Other properties, such as dihedral-angle fluctuations and backbone atom-position fluctuations, converged on an intermediate timescale of hundreds of picoseconds. Root-mean-square deviations of the simulated protein molecules from the starting X-ray structure required of the order of 1 ns to reach a plateau. Longer simulations would be necessary to obtain convergence for all molecular properties. The convergence of quickly relaxing properties of the system, such as the energies, is not a reliable indicator of the degree of global convergence in such a molecular-dynamics simulation.

The *GROMOS*96 force field used in this simulation largely reproduces the secondary structure and the relative internal mobility of ubiquitin. The simulation does, however, overestimate the magnitude of the fluctuations in the most mobile regions of the protein. The different protein molecules were observed to translate and rotate relative to one another during this simulation. This indicates that the force field would not be able to reproduce the experimental melting temperature of this crystal under the conditions simulated.

The authors wish to thank Dr Thomas Huber for fruitful discussions and Dr Alan Mark for critical reading of the manuscript. Financial support was obtained from the Schweizerischer Nationalfonds (Project 21-41875.94), which is gratefully acknowledged.

Chapter 20.2. Molecular-dynamics simulations of biological macromolecules

C. B. Post and V. M. Dadarlat

20.2.1. Introduction

Molecular dynamics (MD) is the simulation of motion for a system of particles. Advances in the theory of atomic interactions and the increasing availability of high-power computers have led to rapid development of this field and greater understanding of macromolecular motions. In the earliest molecular-dynamics simulations of protein molecules (McCammon *et al.*, 1977; McCammon & Harvey, 1987), the systems were greatly simplified in order to fit within the computing capabilities of that time. Simplifications included the exclusion of water molecules and even of explicit hydrogen atoms; the effect of hydrogen atoms was built into the heavy-atom properties using so-called extended-atom parameters. Simulation time periods were limited to tens of picoseconds for systems of less than 10^3 atoms. Modern simulations, by contrast, are based on improved force fields (MacKerell *et al.*, 1998) and benefit from considerable development in algorithms. In addition, the possible size and time period of simulations have increased by orders of magnitude; large systems of the order of 10^4 atoms (including explicit solvent molecules) and nanosecond time periods are accessible. With dedicated computer time, the microsecond regime is possible (Duan & Kollman, 1998). Interestingly, the first 100 ps simulation of an enzyme complex was of hen egg-white lysozyme (Post *et al.*, 1986), the first enzyme whose structure was solved by X-ray crystallography. Then the simulation required several months of dedicated time on a Cray supercomputer, but now it can be accomplished in less than a week on a common workstation.

A consequence of this enormous growth in computing power has been the particularly successful application of molecular dynamics of biological molecules to three-dimensional structure determination and refinement. It is now practical to use molecular dynamics, in combination with crystallographic and NMR data, to search the large conformational space of proteins and nucleic acids to find structures consistent with the data and to improve the agreement with the data. The advantages of molecular dynamics over manual rebuilding and least-squares refinement are the abilities to overcome the local minimum problem in an automated fashion and to search the complex conformational space of a macromolecule more extensively (Brünger *et al.*, 1987).

20.2.2. The simulation method

Molecular mechanics, whereby the energy of the system is expressed in classical terms as a function of atomic coordinates, is well established as a useful approach for describing atomic interactions (Brooks *et al.*, 1988; Goodfellow & Levy, 1998). Owing to the size of proteins and nucleic acids, the potential-energy function for large biomolecules is empirically based rather than derived from quantum-mechanical calculations. The total force on each atom, $\mathbf{F}_i$, is calculated from the gradient, or the first derivative of this potential energy, with respect to the atomic coordinates. The motion of the atom resulting from the net force is described by Newton's equation of motion,

$$\mathbf{F}_i = m_i\mathbf{a}_i, \qquad (20.2.2.1)$$

where m_i is the mass of atom i and $\mathbf{a}_i$ is the acceleration. Integration of equation (20.2.2.1) gives

$$\mathbf{r}_i(t+\Delta t) = \mathbf{r}_i(t) + \mathbf{v}_i(t)\Delta t + \mathbf{F}_i(t)(\Delta t)^2/(2m_i), \qquad (20.2.2.2)$$

where Δt is the time step in the integration, $\mathbf{r}_i(t+\Delta t)$ is the atomic position at time $(t+\Delta t)$, given the position $\mathbf{r}_i(t)$ at time t, and $\mathbf{v}_i(t)$ is the velocity. The forces on the particles change continuously so that a numerical solution of the equation is required. The Verlet algorithm (Verlet, 1967) or a variation, Leapfrog, is commonly used.

20.2.3. Potential-energy function

20.2.3.1. *Empirical energy*

The central element of simulations is the interaction potential between atoms as a function of atomic position, $\mathbf{r}$. The success of simulations in describing the average structure of proteins and other biological features suggests that such relatively simple potential functions adequately represent proteins and nucleic acids. The empirically based components of the energy function, $E_{\rm empir}$, include geometric terms for bond lengths, bond angles and torsion angles, and non-bonding terms for steric van der Waals interactions and electrostatic interactions. A commonly used energy function is

$$E_{\rm empir} = E_{\rm geom} + E_{\rm nonb}, \qquad (20.2.3.1)$$

$$E_{\rm geom} = \sum_{\rm bonds}(1/2)k_b(b-b_{\rm eq})^2 + \sum_{\rm angles}(1/2)k_\theta(\theta-\theta_{\rm eq})^2 + \sum_{\rm torsions}(1/2)k_\varphi[1+\cos(n\varphi-\delta)], \qquad (20.2.3.2)$$

$$E_{\rm nonb} = \sum_{\rm nbpairs}\left(q_iq_j/Dr_{ij}\right) + 4\varepsilon_{ij}\left[\left(\sigma_{ij}/r_{ij}\right)^{12} - \left(\sigma_{ij}/r_{ij}\right)^6\right], \qquad (20.2.3.3)$$

where k_b, k_θ and k_φ are force constants, $b_{\rm eq}$ and $\theta_{\rm eq}$ are equilibrium values for bond lengths, b, and angles, θ, respectively, and φ is the torsion angle of periodicity n and phase δ. The non-bonded terms depend on the interatomic distance r_{ij}, the dielectric constant D, the partial atomic charge q_i, and the van der Waals parameters ε_{ij} and σ_{ij}. The bond-stretching and angle-bending contributions are represented by harmonic potentials, while the energy associated with rotation about a bond, the torsional potential, is modelled by a cosine function [equation (20.2.3.2)]. The electrostatic component of the non-bonded interactions [first term of equation (20.2.3.3)] follows Coulomb's Law, and a Lennard–Jones 6–12 potential function [second term of equation (20.2.3.3)] is used to model steric repulsion and attractive dispersion interactions. $E_{\rm nonb}$, as a sum over pairs of atoms not involved in either a bond or bond angle, requires the use of a pairwise list between atoms. The small contribution from pairs separated by a large distance allows the use of cutoff limits for this list, but at some cost in accuracy.

Initial values for the atomic coordinates and velocities are required to begin the molecular-dynamics simulation. While initial coordinates are obtained from the model built into the electron-density map, it is necessary to generate initial velocities computationally. The most common approach is to assign random

Copyright © 2012 International Union of Crystallography

values for each atom, i, consistent with the temperature chosen for the system: $3kT/2 = (1/2)\sum m_i v_i^2$.

Integration of the equation of motion [equation (20.2.2.1)] also requires specification of the time step Δt. In the case of structure determination, this choice is limited only by the numerical stability of the calculation. Too large a value for Δt results in errors in the integration, manifested by a rapid and unacceptable increase in energy. Whereas a value for Δt of 1 to 2 fs is required for accurate trajectories and strict conservation of the energy, structure-determination protocols can employ larger values and are limited only by the need for numerical stability.

Both the temperature and Δt influence the sampling rate of conformational space. Enhanced sampling increases the rate of convergence to the structure solution. Issues related to sampling are detailed in Chapter 18.2.

20.2.3.2. Particle mesh Ewald

In an MD simulation, the accurate and rapid calculation of long-range electrostatic interactions is a central issue for the correct physical representation of the system. The Coulombic potential [first term of equation (20.2.3.3)] has been used in most cases, but the Coulombic interactions must be limited for practical reasons to a subset of pair interactions so that long-distance interactions are truncated. More recently, the Ewald method has been implemented to avoid the need for truncating the nonbonded pair list while maintaining computational efficiency. The electrostatic energy is calculated using periodic boundary conditions[1] and requires a double summation over all atoms in the central unit cell, as well as their infinite number of periodic images.

The total electrostatic energy of a periodic system with a neutral unit cell containing N point charges $q_1, q_2, \ldots, q_n$ located at positions $\mathbf{r}_1, \mathbf{r}_2, \ldots, \mathbf{r}_N$ is

$$E_{\rm elec} = \tfrac{1}{2}\sum_n{}' \sum_{i=1}^{N}\sum_{j=1}^{N} \frac{q_i q_j}{|\mathbf{r}_{ij} + \mathbf{n}|}.$$

The sum over $|\mathbf{n}|$ takes into account all the periodic unit cells, and $\mathbf{n}$ reflects the shape of the unit cell. For a simple periodic cubic lattice, $\mathbf{n} = (n_x L, n_y L, n_z L)$, where L is the length of the unit cell, and n_x, n_y and n_z are integers. The prime indicates that in the central unit cell the terms $i = j$ are not included. The sum is convergent for very large $|\mathbf{n}|$.

An efficient way of evaluating the triple sum above is represented by the Ewald method. In this method, each point charge is surrounded by a Gaussian charge distribution of opposite sign and same integrated magnitude as the original charge:

$$\rho_i(\mathbf{r}) = -q_i \beta^3 \exp(-\beta^2 \mathbf{r}^2)/\pi^{3/2}.$$

β is inversely proportional to the width of the charge distribution and $\mathbf{r}$ is the position relative to the centre of the distribution. The result of adding this charge distribution is a screening of the electrostatic interactions, so that the interaction between neighbouring charges is effectively short-ranged. A total screened potential is calculated by summation in the real-space lattice over the initial point-charge distribution together with the screening-charge distribution. To end up with the original point-charge distribution, a cancelling distribution having the opposite sign and same functional form as the Gaussian screening distribution must be added. Together, these Gaussian distributions form a smooth varying function of $\mathbf{r}$, which can be approximated by a superposition of continuous functions. The contribution of the cancelling distribution is calculated by adding the Fourier transforms of the distributions in reciprocal space at each point charge and transforming the total back into real space.

The final Ewald expression for the total electrostatic energy contains a real-space sum plus a reciprocal-space sum, minus a self-term introduced by the interaction of the cancelling distribution with itself:

$$E_{\rm elec} = \tfrac{1}{2}\sum_{i=1}^{N}\sum_{j=1}^{N}\left[\sum_n q_i q_i \frac{\operatorname{erfc}(\beta|\mathbf{r}_{ij} + \mathbf{n}|)}{|\mathbf{r}_{ij} + \mathbf{n}|} + q_i q_j \Phi_{\rm rec}(\beta \mathbf{r}_{ij})\right] - \frac{\beta}{\pi^{1/2}}\sum_{i=1}^{N} q_i^2 + J(\mathbf{D}, \mathbf{P}, e').$$

$J(\mathbf{D}, \mathbf{P}, e')$ (de Leeuw *et al.*, 1980) depends on the total dipole moment of the unit cell, the shape of the macroscopic crystal lattice and the dielectric constant of the surrounding medium. The term $\operatorname{erfc}(\beta|\mathbf{r}_{ij} + \mathbf{n}|)$ is the complementary error function which falls to zero as $(\beta|\mathbf{r}_{ij} + \mathbf{n}|)$ increases. The term $\Phi_{\rm rec}(\beta \mathbf{r}_{ij})$ is the reciprocal Ewald sum:

$$\Phi_{\rm rec}(\beta \mathbf{r}_{ij}) = \frac{1}{\pi V}\sum_{m \neq 0} \frac{\exp(-\pi^2 \mathbf{m}^2/\beta^2)}{\mathbf{m}^2} \exp(2\pi i \mathbf{m}\mathbf{r}).$$

V is the volume and $\mathbf{m}$ is a vector in the reciprocal space. The Ewald sum in reciprocal space is the solution to Poisson's equation, with Gaussian charge densities as sources and with periodic boundary conditions. For large β, the only contribution to the sum in the real space comes from the minimum image terms. When β is large, the charge distributions are sharp and the summation in reciprocal space must be done over a large number of reciprocal-space vectors to achieve convergence.

Calculation of the Ewald sum in the original form is slow for large macromolecular solution simulations. The usual implementation of the Ewald summation for calculating electrostatic interaction is an order N^2 algorithm, or at best, $N^{3/2}$ (Christiansen *et al.*, 1993) by adjusting β to optimize computational effort. The particle mesh Ewald (PME) method (Essmann *et al.*, 1995; Darden *et al.*, 1993) is an approximation of the Ewald sum that allows an order $N \log N$ algorithm for the calculation of the total electrostatic energy. This reduction in the number of steps is accomplished by choosing β large enough that atom pairs separated by distances larger than a specified cutoff (9–12 Å) make a negligible contribution to the direct-space sum, which thus becomes an order N computation. Moreover, the reciprocal-space sum is expressed in terms of the electrostatic structure factors. Each atomic charge distribution is approximated by a gridded charge distribution. The resulting approximate structure factors are calculated by a three-dimensional fast Fourier transform applied to the grid. Using an optimized β and grid density for each simulated system, the PME method can compute the electrostatic energy for a periodic boundary system at the same level of accuracy as the classical Ewald summation in a much shorter time (Darden *et al.*, 1993).

20.2.3.3. Experimental restraints in the energy function

For the purpose of structure determination, the potential-energy function used for molecular-dynamics calculation incorporates the information from experimental data in the form of non-physical restraint terms. These restraint terms, introduced to bias the conformational sampling toward structures consistent with the experiment, are used in addition to the total potential function and, in some sense, can fulfil the requirements of a physical term in equation (20.2.2.2) (see below). The experimentally based restraint terms are added to the potential-energy function to give a total effective potential, $E_{\rm tot} = E_{\rm empir} + E_{\rm rest}$. Whereas structure-determination protocols based on NMR data employ a number of types of restraint terms, data from X-ray crystallography provide a single restraint term, $E_{\rm rest} = wE_{\rm Xray}$, the residual between the observed and calculated structure-factor amplitudes; where

---

[1] The periodic boundary conditions method allows for the simulation of the atoms in a central unit cell in the field of image unit cells generated by symmetry operations.

$$wE_{\rm Xray} = w\sum_{hkl}\left(|F_o| - k|F_c|\right)^2,$$

where w and k are scale factors.

20.2.4. Empirical parameterization of the force field

Considerable effort has gone into the development of a number of force fields for use in molecular-dynamics simulations of biomolecules (Jorgensen & Tirado-Rives, 1988; MacKerell *et al.*, 1995, 1998; van Gunsteren *et al.*, 1996). The parameters described here are those of the *CHARMM*22 force field, the force field used in the *X-PLOR* program. Estimation of the force constants, equilibrium values and non-bonding parameters in equations (20.2.3.2) and (20.2.3.3) involves a self-consistent approach that balances the bonding and non-bonding interaction terms among the macromolecule and solvent molecules (MacKerell *et al.*, 1998). A wide range of data are taken into account during an interactive process of optimization in order to adequately account for the extensive and correlated nature of the parameters in a consistent fashion. Small-molecule model compounds representative of proteins or nucleic acids are considered in detail, and a hierarchical approach is applied to extend the parameters to larger molecules with minimal adjustment at the points of connection.

The empirical basis of the parameters is broad. Gas-phase geometries and crystal structures are used to determine equilibrium bond lengths, bond angles, and dihedral phase and periodicity. Vibrational spectra, primarily from gas-phase infrared and Raman spectroscopy, are used to fit values for the force constants. Torsion-angle terms are estimated from relative energies of different conformers of model compounds, such as 4-ethylimidazole and ethylbenzene, based on gas-phase data. In cases where no satisfactory experimental data are available, *ab initio* calculations are used to obtain the required energy surfaces. Adjustments are made to describe the energy barriers and positions of saddle points, as well as the minimum-energy structures.

Optimization of the non-bonded parameters includes fitting the van der Waals and electrostatic terms of equation (20.2.3.3), while maintaining a balance among the protein–protein, water–water and protein–water interactions. The parameterization of the *CHARMM*22 force field is based on the water model and water–water interactions of the *TIP3P* model (Jorgensen *et al.*, 1983). As such, use of this parameter set with another water model will lead to inconsistencies in the balance of intermolecular interactions. Data from dipole moments, heats and free energies of vaporization, solvation and sublimation, and molecular volumes, as well as *ab initio* calculations of interaction energies and geometries are used to optimize intermolecular interactions. Partial charges of atoms are determined by fitting *ab initio* interaction energies and geometries of small-molecule compounds that model the peptide backbone and amino-acid side chains. Magnitudes and directions of dipole-moment values are also used to optimize partial charges. Experimental gas-phase dipole-moment values are used when available, while *ab initio* calculated values are adopted otherwise. The van der Waals parameters are then refined by comparing results of condensed-phase simulations on pure solvents with heats of vaporization and molecular volumes.

The crystallographic restraint term in the potential-energy function, $E_{\rm rest}$, must also be parameterized to optimize the agreement with the experimental structure-factor amplitudes while simultaneously retaining good geometry and non-bonding interactions. Optimization of $E_{\rm rest} = wE_{\rm Xray}$ involves only the estimation of w. Unlike the parameters in $E_{\rm empir}$, w has no physical basis and is usually chosen to make the force due to $E_{\rm rest}$ balance the total force contributed by all terms in $E_{\rm empir}$. As refinement of the structure progresses, these forces, and hence w, necessarily change since the quality, in terms of geometry and non-bonding interactions, of the structure improves and the crystallographic residual is reduced.

20.2.5. Modifications in the force field for structure determination

Simulated-annealing protocols require modification of the parameters to maintain the correct geometry and local structural integrity of the molecule in order to allow heating to very high, non-physical temperatures for several thousand integration steps. Such modifications are acceptable in the case of structure determination since the primary goal is to define the optimum equilibrium structure in best agreement with the crystallographic or NMR data. Simulations intended to reproduce the fluctuations or dynamic properties of the system must employ carefully defined parameters without such modifications. These modifications include substantial increases in the force constants for bond lengths and angles, *e.g.*, factors of two to ten are used in the parameters specified in the *X-PLOR* file parallhdg.pro. A number of improper torsional terms are added to maintain proper chirality.

The specific terms in $E_{\rm nonb}$ are also modified for the purpose of structure determination. In this methodology, the goal is to converge efficiently to a model that satisfies the experimental data, rather than to obtain an accurate description of the conformational surface, such as estimating fluctuations and equilibrium distributions. Alterations in $E_{\rm nonb}$ include the replacement of the computationally expensive $E_{\rm vdW}$ by a quartic or harmonic repulsive term, which prevents steric conflict among atoms, but ignores dispersive attraction. The electrostatic term, $E_{\rm elec}$, is frequently excluded altogether, since the $1/\mathbf{r}$ dependence of the Coulombic potential allows charge interactions to dominate the interatomic forces far from the global minimum in a fashion that hinders movement toward the global minimum. Exclusion of this important physical property of biological systems is possible, because the crystallographic structure factors contain sufficient information to reflect adequately the imprint of electrostatics on the average structure.

20.2.6. Internal dynamics and average structures

It is most often the goal of the structural biologist to define a single average structure of a macromolecule. The well recognized internal motions arising from thermal fluctuations of a macromolecule may be necessary for function, but, nonetheless, the methods of structure determination generally aim to model a single average structure. Internal motions range from the high frequency, small amplitude motions (*i.e.* those modelled by crystallographic B values) to low frequency, larger amplitude motions of loops and whole domains. Some studies (Kuriyan *et al.*, 1986; Post, 1992) have examined the validity of the assumptions about fast timescale motions made by the methods of structure determination. It is reasonable that some of the differences between the structure solutions of a protein obtained by NMR spectroscopy and X-ray crystallography are due to differences in the effects of internal motions. The application of molecular-dynamics algorithms for structure determination has allowed the use of protocols that account for effects of internal motions by employing time-averaged restraints (Schiffer *et al.*, 1995).

20.2.7. Assessment of the simulation procedure

Equation (20.2.3.1) is a reasonable representation of the energy function of proteins. This point is illustrated here with results from 0.8 ns molecular-dynamics simulations of hen egg-white lysozyme (PDB entry 1lzt, 1.97 Å resolution), bovine pancreas ribonuclease A (5rsa, 2.0 Å resolution), bovine α-lactalbumin (1hfz, 2.3 Å resolution) and trypsin (2ptn, 1.55 Å resolution). [The coordinates for bovine α-lactalbumin were kindly provided by K. R. Acharya prior to their publication (Pike *et al.*, 1996).]

The proteins were fully hydrated, and the simulations were calculated with the *CHARMM*22 force field, using truncated octahedron periodic boundary conditions. The four proteins were overlaid with bulk water from an equilibrated simulation, and a 10 ps trajectory was calculated for the rearrangement of the water molecules around the protein with fixed protein atoms. The number of water molecules (4000 to 6000) required to hydrate the protein varied with the protein size (123–223 residues) and shape, with at least four layers of water molecules between the peripheral protein atoms and the walls of the boxes. The simulations were performed at constant pressure and temperature ($T = 300$ K and $p = 1$ atm) using the extended-system algorithms (Hoover, 1985; Nose, 1984) implemented in *CHARMM*. The 300 K constant temperature was maintained by coupling to an external bath, with a coupling constant of 25 ps. The *SHAKE* algorithm (Ryckaert *et al.*, 1977) was used to constrain bond lengths between hydrogen atoms and heavy atoms, allowing for a time step of 2 fs in the integration of the equations of motion. A non-bonded cutoff of 12 Å was used for the Lennard–Jones potential calculation. The electrostatic forces and energies were computed using the PME method (Darden *et al.*, 1993; Essmann *et al.*, 1995). The PME charge grid spacing was 0.7 Å, and the charge grid was interpolated with the direct sum tolerance set to 4.0×10^{-6}. The non-bonded pair lists were updated every 10 steps. Structures for analysis were saved every 0.1 ps.

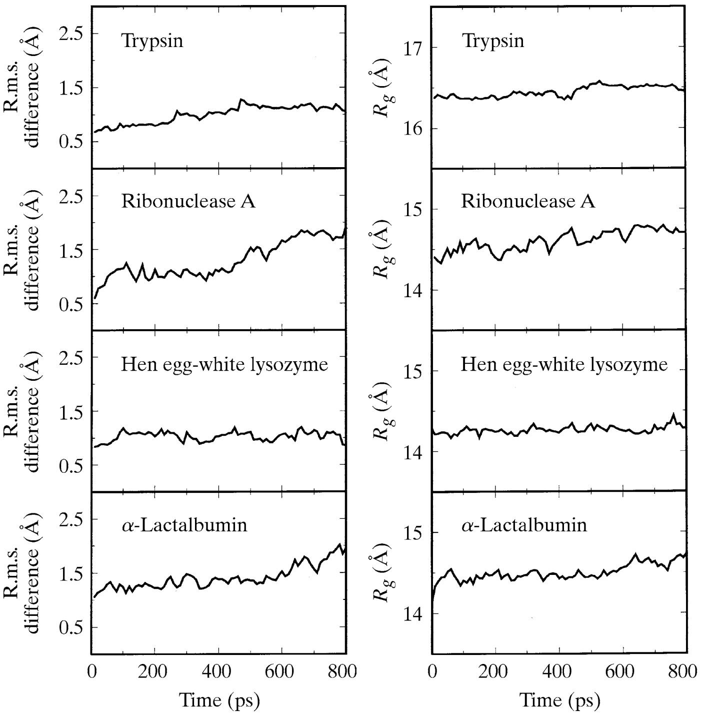

Figure 20.2.7.1
Structural comparison and radii of gyration of various proteins as a function of time in the molecular-dynamics simulation. Left: r.m.s. coordinate differences averaged over main-chain atoms (N, Cα, C) between the energy-minimized crystallographic structure and the simulation snapshot. Right: radii of gyration (R_g).

Fig. 20.2.7.1 shows the deviation during the simulation period of the main-chain coordinates between the simulation structures and the crystallographic starting structure. The r.m.s. coordinate deviations in the case of lysozyme are particularly stable and small: approximately 1.0 Å over the course of the trajectory. Other r.m.s. values are more typical and range from 1.0 to 2.0 Å. The time dependence of other properties, such as the radius of gyration, can also be used to follow the stability and behaviour of a trajectory. These time series, also shown in Fig. 20.2.7.1, are constant. Jumps in such a time series can be used to detect conformational transitions (Post *et al.*, 1989).

Other experimental properties have been compared in the literature with those calculated from molecular-dynamics trajectories. Of particular interest is comparing time-dependent properties measured by NMR spectroscopy. An approach to calculating NMR relaxation rates was recognized early on when development of both the molecular-dynamics simulations of proteins and a model-independent theory for NMR relaxation was started (Levy, Karplus & McCammon, 1981; Levy, Karplus & Wolynes, 1981; Lipari & Szabo, 1982). Since then, the common practice of isotopic labelling of proteins for NMR structure determination has allowed the measurement of numerous NMR relaxation rates, particularly rates that characterize the motion of backbone atoms. Long simulations have been conducted to compare the calculated and experimental values (Abseher *et al.*, 1995; Chatfield *et al.*, 1998; Smith *et al.*, 1995). In a particularly long simulation, an 11 ns trajectory period was used to estimate relaxation rates associated with the motions of the vectors N—H, Cα—H and C—H methyl groups from alanine and leucine (Chatfield *et al.*, 1998). Trends in the general order of mobility of these vectors are reproduced, although a residue-by-residue comparison shows some differences.

20.2.8. Effect of crystallographic atomic resolution on structural stability during molecular dynamics

The variation in r.m.s. deviation between the initial crystallographic structure and the simulation coordinates for different protein trajectories (Fig. 20.2.7.1) raises the question of whether the atomic resolution of the starting X-ray structure influences the magnitude of this deviation. In order to investigate this issue, we calculated trajectories for bovine pancreatic trypsin inhibitor (BPTI), starting with crystallographic structures determined from data at three different atomic resolutions: 1bpi at 1.1 Å resolution (Parkin *et al.*, 1999), 6pti at 1.7 Å resolution (Wlodawer *et al.*, 1987) and 1bhc at 2.7 Å resolution (Hamiaux *et al.*, 1999). The errors in the atomic coordinates estimated from the Luzzati plots are 0.06 Å for the 1.1 Å resolution structure and 0.41 Å for the 2.7 Å resolution structure. The protocol described in the previous

Table 20.2.8.1
R.m.s. coordinate differences between crystallographic structures and average MD structures

The upper half of the matrix contains values for main-chain atoms, while the lower half contains values for side-chain heavy atoms.

		X-ray structure			Energy-minimized X-ray structure			Average MD structure		
		1.1 Å	1.7 Å	2.7 Å	1.1 Å	1.7 Å	2.7 Å	1.1 Å	1.7 Å	2.7 Å
X-ray structure	1.1 Å		0.54	0.51	0.4	0.61	0.7	0.97	1.09	1.13
	1.7 Å	1.5		0.41	0.6	0.42	0.57	1.11	1.14	1.11
	2.7 Å	1.62	1.43		0.59	0.57	0.48	1.12	1.12	1.11
Energy-minimized X-ray structure	1.1 Å	0.57	2.81	2.06		0.59	0.63	1.01	1.15	1.13
	1.7 Å	1.5	0.79	1.68	1.47		0.58	1.12	1.13	1.13
	2.7 Å	1.72	1.65	0.99	1.78	1.77		1.28	1.11	1.11
Average MD structure	1.1 Å	1.89	2.18	2.45	1.94	2.87	2.66		1.06	1.08
	1.7 Å	2.53	2.28	2.49	2.52	2.33	2.52	2.22		0.87
	2.7 Å	2.15	2.05	1.9	2.17	2.13	1.85	2.17	2.15	

section was followed for simulations starting with each of the three crystallographic structures over a 500 ps simulation time. The net charge of +6 e on BPTI was neutralized by adding six chloride anions to the solvated protein system, thus accomplishing the ideal conditions for a PME calculation for the electrostatic interaction. The truncated octahedra contain approximately 3700 water molecules, and the total number of atoms in the simulations is over 12 000. The simulations were carried out on an eight-node IBM/SP2 and required 4.5 h of CPU time per 10 ps of dynamics run.

Root-mean-square differences (r.m.s.d.'s) in atomic coordinates were calculated between all pairs of coordinates from the X-ray structures, the energy-minimized X-ray structures and the 10 ps average MD structure obtained near 300 ps of the simulation period. In Table 20.2.8.1, the upper diagonal r.m.s.d. values are the main-chain-atom differences, while the lower diagonal ones are the side-chain-atom differences. The r.m.s.d.'s between the three X-ray structures range from 0.4–0.5 Å for the main-chain atoms and 1.4–1.6 Å for the side-chain atoms. The larger r.m.s. values for averages over side-chain atoms imply alternative side-chain orientations. This degree of structural deviation is visualized with an overlay of the three X-ray structures of BPTI shown on the left-hand side of Fig. 20.2.8.1. Energy minimization with respect to the *CHARMM* force field alters the main-chain atoms of the X-ray structures by approximately 0.4 Å and increases the differences between two X-ray structures to 0.6–0.7 Å. The differences in the main-chain atoms between an MD average structure and an energy-minimized X-ray structure are only somewhat larger: 1.0–1.1 Å. Interestingly, these values are comparable to the values obtained when comparing the three MD average structures: 0.9–1.1 Å. The main-chain structural differences among the three 10 ps average MD structures are shown on the right-hand side of Fig. 20.2.8.1. The general trends observed for main-chain atoms are also found for side-chain atoms. Thus, the differences between the X-ray structures increase somewhat as a result of energy minimization, and the differences between MD average structures and X-ray structures (1.9–2.9 Å) are similar to those between two X-ray structures (1.5–2.8 Å) or two MD average structures (approximately 2.2 Å).

Similar r.m.s. values are found if the starting velocites for a simulation are varied while maintaining the same starting coordinates (Caves *et al.*, 1998); the r.m.s.d.'s obtained from 120 ps MD simulations were 0.7–1.1 Å for the main-chain atoms with respect to the reference X-ray structure and 0.8–1.5 Å between MD individual trajectory averages. The results given in Table

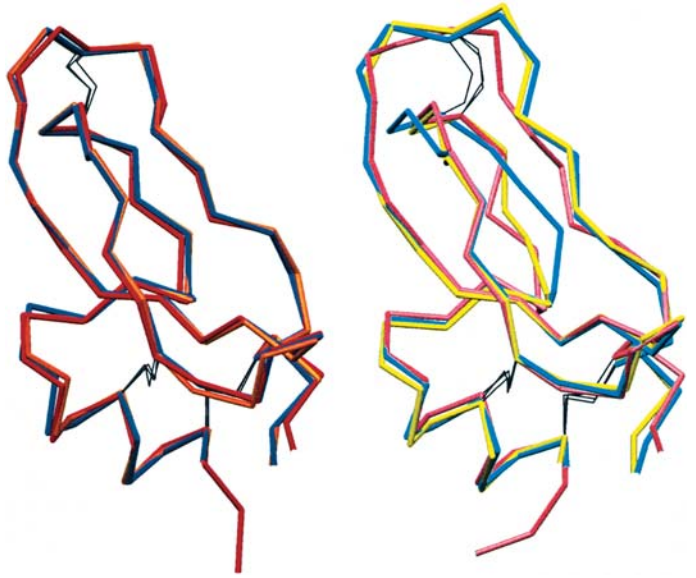

Figure 20.2.8.1
Cα tracings of BPTI. Left: crystallographic structures determined from data at three different resolutions: 1.1 (red), 1.7 (blue) and 2.7 Å (orange). Right: 10 ps average MD structures from simulations initiated with the energy-minimized crystallographic structure determined at 1.1 (pink), 1.7 (cyan) or 2.7 Å (yellow) resolution. The 10 ps average is over coordinates from 290 to 300 ps.

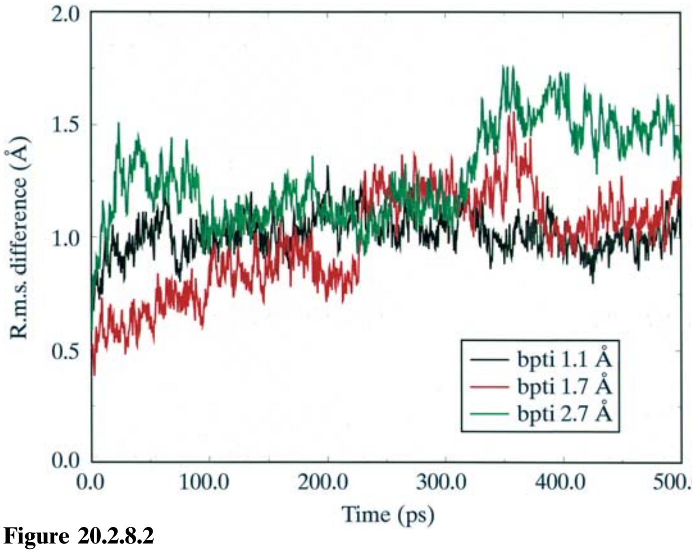

Figure 20.2.8.2
BPTI r.m.s. coordinate differences between the energy-minimized crystallographic structure and MD snapshots from three simulations. A simulation was initiated from the energy-minimized crystallographic structure determined at 1.1 (black), 1.7 (red) or 2.7 Å (green) resolution. The r.m.s.d. is averaged over the main-chain atoms N, Cα and C.

20.2.8.1, together with those of Caves *et al.* (1998), suggest that sampling on the nanosecond timescale largely reflects the conformational variations due to thermal fluctuations that result from a potential-energy surface with multiple minima separated by low barriers (Cooper, 1976). In this context, MD simulations starting with different X-ray structures offer a more extensive sampling of the conformational space of the specific protein than simulations carried out from a single X-ray structure, although this conclusion remains to be demonstrated by a more thorough analysis. Our results do not support the conclusion that overall r.m.s.d.'s between MD average structures and the starting X-ray structures correlate with atomic resolution.

The r.m.s.d.'s between main-chain atoms in the starting X-ray structures and simulation snapshots as a function of time are presented in Fig. 20.2.8.2. The 1.1 Å resolution structure has the most stable trajectory during the 500 ps trajectory, with an average r.m.s. value of 1.01 (9) Å. The 1.7 Å resolution structure has an r.m.s. value of 0.98 (22) Å. In this simulation, the r.m.s.d.'s fluctuate more widely from the average value, with small differences in the first 200 ps, larger ones between 200 and 400 ps, and again smaller ones in the last 100 ps. For the 2.7 Å resolution structure, the average over the simulation is 1.28 (21) Å. From the results presented here, it is concluded that the higher-resolution structures are more stable during MD simulations and have a shorter equilibration period (50 ps for 1.1 Å resolution and over 300 ps for 2.7 Å resolution). This conclusion is consistent with larger errors in the atomic coordinates of X-ray structures determined from lower-resolution data.

PART 21. STRUCTURE VALIDATION

Chapter 21.1. Validation of protein crystal structures

G. J. Kleywegt

21.1.1. Introduction

Owing to the limited resolution and imperfect phase information that macromolecular crystallographers usually have to deal with, building and refining a protein model based on crystallographic data is not an exact science. Rather, it is a subjective process, governed by experience, prejudices, expectations and local practices (Brändén & Jones, 1990; Kleywegt & Jones, 1995*b*, 1997). This means that errors in this process are almost unavoidable, but it is the crystallographer's task to remove as many of these as possible prior to analysis, publication and deposition of the structure. With high-resolution data and good phases, the resulting model is probably more than 95% a consequence of the data, although even at atomic resolution, subjective choices must still be made: which refinement program to use, whether to include alternative conformations, whether to model explicit H atoms, how to model temperature factors, which restraints and constraints to apply, which peaks in the maps to interpret as solvent molecules and how to treat noncrystallographic symmetry (NCS). Once the resolution becomes worse than ~2 Å, this balance shifts and some published protein models appear to have been determined more by some crystallographer's imagination than by any experimental data.

Subjectivity is not necessarily a problem, provided that the crystallographer is experienced, knows what he or she is doing and is aware of the limitations that the experimental data impose on the model. However, even inexperienced people can avoid many of the pitfalls of model building and refinement. Supervisors have a major responsibility in this respect: education is an important factor (Dodson *et al.*, 1996). Students who have built and refined a previously determined structure from scratch as a training exercise will have met most of the problems that can be encountered in real life (Jones & Kjeldgaard, 1997). Apart from hands-on experience, there are many other methods to reduce or avoid errors. These include (1) the use of information derived from databases of well refined structures in model building (Kleywegt & Jones, 1998) [*e.g.* to generate main-chain coordinates from a C$^{\alpha}$ trace (Jones & Thirup, 1986) and side-chain coordinates from preferred rotamer conformations (Ponder & Richards, 1987)]; (2) the use of various sorts of local quality checks (to detect residues that for one or more reasons are deemed 'unusual' and that require further scrutiny and perhaps adjustment; Kleywegt & Jones, 1996*a*, 1997); and (3) the use of global quality indicators [*e.g.* the use of the free *R* value (Brünger, 1992*a*, 1993) to signal major errors, to prevent overfitting, and to monitor the progress of the rebuilding and refinement process (Kleywegt & Jones, 1995*b*; Kleywegt & Brünger, 1996; Brünger, 1997)].

21.1.2. Types of error

At every step of a crystal structure determination, the danger of making mistakes looms (Brändén & Jones, 1990; Janin, 1990). In this laboratory, for instance, a protein other than that intended was once purified (lysozyme instead of cellular retinoic acid binding protein), which obviously made the molecular-replacement problem rather intractable. Similarly, there is at least one published crystallization report of a protein other than for which the crystallographers had hoped: crystals of the light-harvesting complex LH1 actually turned out to be of bacterioferritin (Nunn *et al.*, 1995). There is at least one case in which an incorrect molecular-replacement solution was found that persisted all the way to the final published model, namely that of turkey egg-white lysozyme (Bott & Sarma, 1976). During data collection and processing, space-group assignment errors are occasionally made, such as in the case of chloromuconate cycloisomerase (Hoier *et al.*, 1994; Kleywegt *et al.*, 1996). A more common problem at this stage, however, is weak and/or incomplete data. The importance of complete data sets with a high signal-to-noise ratio and high redundancy for the success of the subsequent structure determination process (phasing, model building and refinement) cannot be overstressed. However, the discussion in this chapter will focus mainly on errors that may creep into a protein model built and refined by a crystallographer. Such errors come in various classes (Brändén & Jones, 1990) and, fortunately, the frequency of each type of error is inversely proportional to its seriousness.

1. In the worst case, the model (or a sub-unit) may essentially be completely wrong. Recently identified examples of this type of problem include asparaginase/glutaminase (Ammon *et al.*, 1988; Lubkowski *et al.*, 1994) and photoactive yellow protein (McRee *et al.*, 1989; Borgstahl *et al.*, 1995).
2. In other cases, secondary-structure elements may have been correctly identified for the most part, but incorrectly connected. This happened, for instance, in the structure determination of D-Ala-D-Ala carboxypeptidase/transpeptidase (Kelly *et al.*, 1986; Kelly & Kuzin, 1995).
3. A fairly common mistake during the initial tracing is to overlook one residue, which leads to a register error (or frame shift). The model is usually brought back into register with the density a bit further down the sequence, where the opposite error is made (*e.g.* an extra residue is inserted into density for a turn). This is a serious error, but it is usually possible to detect and correct it in the course of the refinement and rebuilding process (Kleywegt *et al.*, 1997). However, it is not impossible for such an error to persist, particularly in low-resolution studies. Indeed, in one case in which a published 3.0 Å structure was re-refined, a register error was detected involving about two dozen residues (Hoier *et al.*, 1994; Kleywegt *et al.*, 1996).
4. Sometimes the primary sequence used by the crystallographer contains one or more mistakes. These may arise from post-translational modifications, from sequencing errors, from the absence of a published amino-acid sequence at the time of tracing, from unanticipated cloning artifacts or simply from trivial 'transcription artifacts'. In this laboratory,

Copyright © 2012 International Union of Crystallography

the latter occurred during the refinement of human α-class glutathione S-transferase A1-1 (Sinning *et al.*, 1993), where one glycine residue had mistakenly been typed in as aspartate. Fortunately, the error revealed itself even at low resolution (2.6 Å), because the model was refined conservatively. In this case, the group of side-chain atoms obtained a very high *B* factor, in contrast to the very low *B* factor for the grouped main-chain atoms.

(5) The most common type of model-building error is locally incorrect main-chain and/or side-chain conformations. Such errors are easy to make in low-resolution maps calculated with imperfect phases. Moreover, multiple conformations are often unresolved even at moderately high resolution (~2 Å), which further complicates the interpretation of side-chain density. Nevertheless, many of them can be avoided through the use of information derived from databases (such as rotamer conformations; Jones *et al.*, 1991; Zou & Mowbray, 1994; Kleywegt & Jones, 1998) and careful rebuilding and refinement protocols (Kleywegt & Jones, 1997).

(6) Various types of error (possibly, to some extent, compensating ones) can be introduced during refinement, particularly if a satisfactorily low value for the conventional crystallographic *R* value is desired (Kleywegt & Jones, 1995*b*). This can always be achieved (even for models that have been deliberately traced backwards through the density; Jones *et al.*, 1991; Kleywegt & Jones, 1995*b*; Kleywegt & Brünger, 1996) by removing data that do not agree well with the model (through a resolution and σ cutoff), by not exploiting the redundancy of noncrystallographic symmetry properly (Kleywegt & Jones, 1995*b*; Kleywegt, 1996), by using an inappropriate temperature-factor model, by introducing alternative conformations and refining occupancies when these are not warranted by the information content of the data, by sprinkling the model with solvent molecules, and by reducing the weight given to the geometric and other restraints relative to the weight given to the crystallographic data.

One should realise that making errors is almost unavoidable (given the fact that one usually deals with limited resolution and less than perfect phases). The purpose of refinement and rebuilding is to detect and fix the errors to obtain the best possible final model that will be interpreted in terms of the biological role of the protein. Nevertheless, sometimes errors do persist into the publication and the deposited model. This may be a consequence of factors such as (Jones & Kjeldgaard, 1997):

(1) inexperienced, under-supervised people who do the work (and have a supervisor who may be in a hurry to publish);
(2) computer programs used as black boxes;
(3) new methods not adopted until the limitations of older ones have been experienced;
(4) intermediate models not subjected to critical and systematic quality analysis;
(5) use of 'quality indicators' that are strongly correlated with parameters that are restrained during refinement (r.m.s. deviation of bond lengths and angles from ideal values, r.m.s. ΔB for bonded atoms *etc.*).

21.1.3. Detecting outliers

21.1.3.1. Classes of quality indicators

Many statistics, methods and programs were developed in the 1990s to help identify errors in protein models. These methods generally fall into two classes: one in which only coordinates and *B* factors are considered (such methods often entail comparison of a model to information derived from structural databases) and another in which both the model and the crystallographic data are taken into account. Alternatively, one can distinguish between methods that essentially measure how well the refinement program has succeeded in imposing restraints (*e.g.* deviations from ideal geometry, conventional *R* value) and those that assess aspects of the model that are 'orthogonal' to the information used in refinement (*e.g.* free *R* value, patterns of non-bonded interactions, conformational torsion-angle distributions). An additional distinction can be made between methods that provide overall (global) statistics for a model (such methods are suitable for monitoring the progress of the refinement and rebuilding process) and those that provide information at the level of residues or atoms (such methods are more useful for detecting local problems in a model). It is important to realise that almost all coordinate-based validation methods detect *outliers* (*i.e.* atoms or residues with unusual properties): to assess whether an outlier arises from an *error* in the model or whether it is a genuine, but unusual, *feature* of the structure, one must inspect the (preferably unbiased) electron-density maps (Jones *et al.*, 1996)!

In this section, some quality indicators will be discussed that have been found to be particularly useful in daily protein crystallographic practice for the purpose of detecting problems in intermediate models. Section 21.1.7 provides a more extensive discussion of many of the quality criteria that are or have been used by macromolecular crystallographers.

21.1.3.2. Local statistics

From a practical point of view, these are the most useful for the crystallographer who is about to rebuild a model. Examples of useful quality indicators are:

(1) The real-space fit (Jones *et al.*, 1991; Chapman, 1995; Jones & Kjeldgaard, 1997; Vaguine *et al.*, 1999), expressed as an *R* value or as a correlation coefficient between 'observed' and calculated density. This property can be calculated for any subset of atoms, *e.g.* for an entire residue, for main-chain atoms or for side-chain atoms. It is best to use a map that is biased by the model as little as possible [*e.g.*, a σ_A-weighted map (Read, 1986), an NCS-averaged map (Kleywegt & Read, 1997) or an omit map (Bhat & Cohen, 1984; Hodel *et al.*, 1992)]. In practice, the real-space fit is strongly correlated with the atomic temperature factors, even though these are not used in the calculations.

(2) The Ramachandran plot (Ramakrishnan & Ramachandran, 1965; Kleywegt & Jones, 1996*b*). Residues with unusual main-chain φ, ψ torsion-angle combinations that do not have unequivocally clear electron density are almost always in error. However, one should keep in mind that the error may have its origin in (one of) the neighbouring residues. For instance, if the peptide O atom of a residue is pointing in the wrong direction, the φ value for the next residue may be off by 150–180° (Kleywegt, 1996; Kleywegt & Jones, 1998).

(3) The pep-flip value (Jones *et al.*, 1991; Kleywegt & Jones, 1998). This statistic measures the r.m.s. distance between the peptide O atom of a residue and its counterparts found in a database of well refined high-resolution structures that occur in parts of those structures with a similar local C^α backbone conformation. If the pep-flip value is large (*e.g.* >2.5 Å), the residue is termed an outlier, but whether it

is an error can only be determined by inspecting the local density.

(4) The rotamer side-chain fit value (Jones *et al.*, 1991; Kleywegt & Jones, 1998). This statistic measures the r.m.s. distance between the side-chain atoms of a residue and those in the most similar rotamer conformation for that residue type. A value greater than ~1.0–1.5 Å signals an outlier. In many cases (particularly, but not exclusively, at low resolution), a non-rotamer side chain can easily be replaced by a rotamer conformation, perhaps in conjunction with a slight rigid-body movement of the entire residue or with some adjustment of the side-chain torsion angles (Zou & Mowbray, 1994; Kleywegt & Jones, 1997).

(5) Hydrogen-bonding analysis. The correct orientation of histidine, asparagine and glutamine side chains cannot usually be inferred from electron density alone. Inexperienced crystallographers can benefit from suggestions based on the analysis of hydrogen-bonding networks (Hooft *et al.*, 1996*b*), although every case should be examined critically (*e.g.* the program does not know about solvent molecules that have not yet been added to the model or that cannot be placed because of the limitations of the data; in addition, sometimes an amino group may be interacting with an aromatic side chain).

In addition to these criteria, residues with other unusual features should be examined in the electron-density maps for the crystallographer to be able to decide whether they are in error. Such features may pertain to unusual temperature factors, unusual occupancies, unusual bond lengths or angles, unusual torsion angles or deviations from planarity (*e.g.* for the peptide plane), unusual chirality (*e.g.* for the C^α atom of every residue type except glycine), unusual differences in the temperature factors of chemically bonded atoms, unusual packing environments (Vriend & Sander, 1993), very short distances between non-bonded atoms (including symmetry mates), large positional shifts during refinement, unusual deviations from noncrystallographic symmetry (Kleywegt & Jones, 1995*b*; Kleywegt, 1996) *etc.*

21.1.3.3. Global statistics

The crystallographic *R* value used to be the major global quality indicator until it was realised that it can easily be fooled, especially at low resolution (Brändén & Jones, 1990; Jones *et al.*, 1991; Brünger, 1992*a*; Kleywegt & Jones, 1995*b*). The free *R* value, introduced by Brünger (1992*a*, 1993), has been shown to be much more reliable and harder to manipulate (Kleywegt & Brünger, 1996; Brünger, 1997). It is excellently suited for monitoring the progress of refinement, for detecting major problems with model or data and for helping reduce over-fitting of the data (which occurs if many more parameters are refined in a model than is warranted by the information content of the crystallographic data). Moreover, the free *R* value can be used to estimate the coordinate error of the final model (Kleywegt *et al.*, 1994; Kleywegt & Brünger, 1996; Brünger, 1997; Cruickshank, 1999).

In addition, the average or r.m.s. values for many of the local statistics, their minimum or maximum values or the percentage of outliers can be quoted and used to obtain an impression of the overall quality of the model and the overall fit of the model to the data.

21.1.4. Fixing errors

The object of model rebuilding is generally twofold: (1) to make the model as complete and detailed as the data will allow one to do confidently (*e.g.* to add previously unmodelled loops, ligands, water molecules *etc.*) and (2) to remove errors. At first glance, it may not seem all that important to fix each and every side chain and to correct all peptide O atoms that are pointing in the wrong direction, but one should keep in mind that an error in the scattering factor (atom type or charge), position or *B* factor of even a single atom will be detrimental to the entire model. Particularly in the early stages of model rebuilding and refinement, one often finds that after an extensive round of rebuilding followed by more refinement, the density improves dramatically and new features become clear. One should also keep in mind that incorrect features of a model may be very persistent and become 'self-fulfilling prophecies', a phenomenon known as 'model bias' (Ramachandran & Srinivasan, 1961; Read, 1986, 1994, 1997; Hodel *et al.*, 1992). This is particularly relevant in cases where unbiased phase information (*e.g.* SIRAS, MIR or MAD phases, or phases obtained after NCS or multiple-crystal averaging) is not available.

For error detection to be effective, it is best not to approach the rebuilding process in a haphazard way (Kleywegt & Jones, 1997). *O* users can employ a program called *OOPS* (Kleywegt & Jones, 1996*a*) to carry out this task in a systematic yet convenient fashion. This program uses information calculated by *O* (*e.g.* pep-flip and real-space fit values) and retrieves or derives other information from a PDB file of the current model (*e.g.* temperature factors, Ramachandran plot, changes with respect to the previous model). Moreover, results from a coordinate-based quality check by the *WHAT IF* program (Vriend, 1990; Hooft *et al.*, 1996) can be included. In all, several dozen quality indicators can be used and plots and statistics for many of these can be produced by the program. The program's most useful feature, however, is that it will generate *O* macros that when executed in *O* will take the crystallographer on a journey to all the residues that may require attention because they are outliers for one or more quality criteria. This makes the rebuilding process often faster and certainly more efficient and focused than a residue-by-residue walk through the model. In addition, it teaches inexperienced crystallographers to recognize and diagnose common model errors.

If a residue is an outlier for a certain criterion, the crystallographer has to inspect the local density and the structural context and decide the course of action. If the residue is in a region of the model in which many residues are outliers for many criteria, there may be something seriously wrong locally (for instance, there could be a register error), possibly because the density is poor. If there is poor density for several residues in a row, the crystallographer might consider leaving these residues out of the model for the next refinement round or cutting off the side chains at the C^β atoms. Sometimes local errors are correlated, such as a pep-flip error in one residue and a Ramachandran violation for its C-terminal neighbour, or a residue with a non-rotamer conformation and high temperature factors in conjunction with a poor real-space fit. *O* contains many tools to manipulate individual residues and atoms (Jones *et al.*, 1991; Jones & Kjeldgaard, 1994, 1997; Kleywegt & Jones, 1997), *e.g.* to flip a peptide plane, to replace a side chain by a rotamer conformation, to change side-chain torsion angles in order to optimize the fit to the density, to move groups of atoms, to use real-space refinement on a single residue or a zone of residues, to 'mutate' a residue to alanine *etc*. Together they constitute a toolbox with which many problems, once recognized, can be fixed relatively effortlessly (Kleywegt & Jones, 1997).

21.1.5. Preventing errors

As with everything else, when it comes to building a model of a protein, prevention of errors is the best medicine. Some general guidelines can be given (Dodson *et al.*, 1996; Kleywegt & Jones, 1997).

(1) Try to obtain the best possible set of data and the best possible set of phases for those data. If the structure has noncrystallographic symmetry (or if multiple crystal forms are available), use electron-density averaging to remove model bias and to reduce phase errors (Kleywegt & Read, 1997). In the absence of noncrystallographic symmetry, use maps that are biased by the model as little as possible [*e.g.* σ_A-weighted (Read, 1986) or omit maps (Bhat & Cohen, 1984; Bhat, 1988; Hodel *et al.*, 1992)]. If experimental phase information is available, keep and consult the experimental map(s). Experimental phases can also be used throughout the refinement process to alleviate or prevent some problems.

(2) Use databases to construct the initial model (or new parts of the model; Jones *et al.*, 1991; Kleywegt & Jones, 1998). All the crystallographer needs to do is to roughly place the C^α atoms in the density. The model-building program can then 'recycle' well refined high-resolution structures to place the main-chain atoms. Similarly, side-chain conformations should initially be chosen from the set of preferred rotamers for each residue type, perhaps in combination with a rigid-body rotation of the entire residue around its C^α atom and/or with minor adjustment of the torsion angles of long side chains (arginine, lysine *etc.*).

(3) After every cycle of refinement, carry out a critical analysis of the quality of the current model. This entails the calculation of properties such as those discussed in Section 21.1.3 and the inspection of the residues that are outliers for any of them, as described in Section 21.1.4. Be conservative during rebuilding, especially when the model is incomplete and possibly full of errors.

(4) Design a refinement protocol that is appropriate for the available data. If NCS restraints do not give a significantly better free *R* value than NCS constraints, then use constraints. If NCS restraints are to be employed, then use the experimental map to design a suitable NCS-restraint scheme (Kleywegt, 1999). Avoid the temptation to model alternative conformations in low-resolution maps or to place putative solvent molecules in every local maximum of the ($F_o - F_c$, α_c) difference map. In other words, be conservative and remember that the maxim 'where freedom is given, liberties are taken' is highly applicable to refinement programs (Hendrickson & Konnert, 1980; Kleywegt & Jones, 1995*b*).

(5) Adopt methodological advances as soon as they become available. Several innovations have only been slowly accepted by the mainstream (*e.g.* the use of databases in building and rebuilding, the use of the free *R* value, the use of electron-density averaging in molecular-replacement cases, bulk-solvent modelling). The most prominent recent development is the use of likelihood-based refinement programs (Bricogne & Irwin, 1996; Pannu & Read, 1996; Murshudov *et al.*, 1997; Adams *et al.*, 1997; Pannu *et al.*, 1998). These programs produce better models and maps and considerably reduce over-fitting (as assessed by the difference between the free and conventional *R* values).

(6) Most importantly, the crystallographer should be hypercritical towards the fruits of his or her own labour. Every intermediate model is a hypothesis to be shot down (Jones & Kjeldgaard, 1994). The crystallographer should be more critical than the supervisor, the supervisor more critical than the referee and the referee more critical than the casual reader. It goes without saying that the reader, casual or not, should have access to model coordinates, experimental data and electron-density maps!

21.1.6. Final model

Once the refinement is finished [*i.e.* once the ($F_o - F_c$, α_c) difference map is featureless (Cruickshank, 1950) and parameter shifts in further refinement cycles are negligibly small], three tasks remain: validation of the final model, description and analysis of the structure, and deposition of the model coordinates and the crystallographic data with the Protein Data Bank (Bernstein *et al.*, 1977).

Until a few years ago, validation of the final model typically entailed calculating the conventional *R* value, r.m.s. deviations from ideal values of bond lengths and angles, average temperature factors, and a Luzzati-type estimate of coordinate error. Kleywegt & Jones (1995*b*) showed that these statistics are not necessarily even remotely related to the actual quality of a model. Based on these criteria, a backwards-traced protein model was of higher apparent quality than a carefully refined correct model. After this, the realisation sunk in that the best validation criteria are those that assess aspects of the model that are 'orthogonal' to the information used during model refinement and rebuilding. For instance, the main-chain φ and ψ torsion angles are usually not restrained during refinement; this makes the Ramachandran plot such a powerful validation tool (Kleywegt & Jones, 1996*b*, 1998). Other examples of useful independent tests include the profile method of Eisenberg and co-workers (Lüthy *et al.*, 1992), the directional atomic contact analysis method of Vriend & Sander (1993) and the threading-potential method of Sippl (1993).

In general, all quality checks provide necessary, but in themselves insufficient, indications as to whether or not a model is essentially correct. A truly good model should make sense with respect to what is currently known about physics, chemistry, crystallography, protein structures, statistics and (last, but not least) biology and biochemistry (Kleywegt & Jones, 1995*a*). A good model will typically score well on most if not all validation criteria, whereas a poor one will score poorly on many criteria. The same is true at the level of residues: a poor or erroneous region in a model will be characterized by violations of many residue-level quality criteria (Kleywegt & Jones, 1997).

21.1.7. A compendium of quality criteria

In this section, some of the quality and validation criteria that have been used by macromolecular crystallographers are summarized (for more detailed information, the reader is referred to the primary literature). When judging how useful or powerful these criteria are in a certain case, one should keep in mind that any criterion that has been used explicitly or implicitly during model refinement (*e.g.* geometric restraints) or rebuilding (*e.g.* rotamer libraries) does *not* provide a truly independent check on the quality of the model.

Many, but not all, of the criteria discussed below pertain specifically to protein models. Comparatively little work has been performed on the validation of nucleic acid models, although there are indications that there is a need for such procedures (Schultze & Feigon, 1997). The situation would appear to be even worse for hetero-entities (*e.g.* ligands, inhibitors, cofactors, covalent attachments, saccharides, metals, ions; van Aalten *et al.*, 1996; Kleywegt & Jones, 1998).

21.1.7.1. Data quality

Although many quality and validation criteria have been developed for assessing coordinate sets of protein models, comparatively few criteria are available for assessing the quality of the crystallographic data.

21.1.7.1.1. Merging R values

Possibly the most common mistake in papers describing protein crystal structures is an incorrectly quoted formula for the merging R value (calculated during data reduction),

$$R_{\rm merge} = \sum_h \sum_i |I_{h,i} - \langle I_h\rangle| / \sum_h \sum_i I_{h,i},$$

where the outer sum (h) is over the unique reflections (in most implementations, only those reflections that have been measured more than once are included in the summations) and the inner sum (i) is over the set of independent observations of each unique reflection (Drenth, 1994). This statistic is supposed to reflect the spread of multiple observations of the intensity of the unique reflections (where the multiple observations may derive from symmetry-related reflections, different images or different crystals). Unfortunately, $R_{\rm merge}$ is a very poor statistic, since its value increases with increasing redundancy (Weiss & Hilgenfeld, 1997; Diederichs & Karplus, 1997), even though the signal-to-noise ratio of the average intensities will be higher as more observations are included (in theory, an N-fold increase of the number of independent observations should improve the signal-to-noise ratio by a factor of $N^{1/2}$). At high redundancy, the value of $R_{\rm merge}$ is directly related to the average signal-to-noise ratio (Weiss & Hilgenfeld, 1997): $R_{\rm merge} \simeq 0.8/\langle I/\sigma(I)\rangle$.

Diederichs & Karplus (1997) have suggested a number of alternative measures that lack most of the drawbacks of $R_{\rm merge}$. Their statistic $R_{\rm meas}$ is similar to $R_{\rm merge}$, but includes a correction for redundancy (m),

$$R_{\rm meas} = \sum_h [m/(m-1)]^{1/2} \sum_i |I_{h,i} - \langle I_h\rangle| / \sum_h \sum_i I_{h,i}.$$

Another statistic, the pooled coefficient of variation (PCV), is defined as

$${\rm PCV} = \sum_h \{[1/(m-1)] \sum_i (I_{h,i} - \langle I_h\rangle)^2\}^{1/2} / \sum_h \langle I_h\rangle.$$

Since PCV = $1/\langle I/\sigma(I)\rangle$, this quantity also provides an indication as to whether the standard deviations $\sigma(I)$ have been estimated appropriately. Finally, the statistic $R_{\rm mrgd\text{-}F}$, used for assessing the quality of the reduced data, enables a direct comparison of this merging R value with the refinement residuals R and $R_{\rm free}$.

Ideally, merging statistics should be quoted for all resolution shells (which should not be too broad), as well as for the entire data set. However, as a minimum, the values for the two extreme (low- and high-resolution) shells and for the entire data set should be reported.

21.1.7.1.2. Completeness

Data completeness can be assessed by calculating what fraction of the unique reflections within a range of Bragg spacings that could in theory be observed has actually been measured. Ideally, completeness should be quoted for all resolution shells (which should not be too broad), as well as for the entire data set. However, as a minimum, the values for the two extreme (low- and high-resolution) shells and for the entire data set should be reported.

21.1.7.1.3. Redundancy

Redundancy is defined as the number of independent observations (after merging of partial reflections) per unique reflection in the final merged and symmetry-reduced data set. Ideally, average redundancy should be quoted for all resolution shells (which should not be too broad), as well as for the entire data set. However, as a minimum, the values for the two extreme (low- and high-resolution) shells and for the entire data set should be reported.

21.1.7.1.4. Signal strength

The average strength or significance of the observed intensities can be expressed in different ways. Values that are often quoted include the percentage of reflections for which $I/\sigma(I)$ exceeds a certain value (usually 3.0) and the average value of $I/\sigma(I)$. Ideally, these numbers should be quoted for all resolution shells (which should not be too broad), as well as for the entire data set. However, as a minimum, the values for the two extreme (low- and high-resolution) shells and for the entire data set should be reported.

21.1.7.1.5. Resolution

The nominal resolution limits of a data set are chosen by the crystallographer, usually at the data-processing stage, and ought to reflect the range of Bragg spacings for which useful intensity data have been collected. Unfortunately, owing to the subjective nature of this process, resolution limits cannot be compared meaningfully between data sets processed by different crystallographers. Careful crystallographers will take factors such as shell completeness, redundancy and $\langle I/\sigma(I)\rangle$ into account, whereas others may simply look up the minimum and maximum Bragg spacing of all observed reflections. Bart Hazes (personal communication) has suggested defining the effective resolution of a data set as that resolution at which the number of observed reflections would constitute a 100% complete data set. Alternatively, Vaguine *et al.* (1999) define the effective (or optical) resolution as the expected minimum distance between two resolved peaks in the electron-density map and calculate this quantity as $2\Delta_P/2^{1/2}$, where Δ_P is the width of the origin Patterson peak. One day, hopefully, the term 'resolution' will be replaced by an estimate of the information content of data sets. Randy Read (personal communication) has carried out preliminary work along these lines.

21.1.7.1.6. Unit-cell parameters

The accuracy of unit-cell parameters has been shown to be grossly overestimated for small-molecule crystal structures (Taylor & Kennard, 1986). Not intimidated by this observation, some macromolecular crystallographers routinely quote unit-cell axes of 100–200 Å with a precision of 0.01 Å. An analysis of several high-resolution protein crystal structures has revealed that surprisingly large errors in the unit-cell parameters appear to be quite common (at least if synchrotron sources are used for data collection; EU 3-D Validation Network, 1998). Such errors can be detected *a posteriori* by checking if the bond lengths in a model show any systematic, perhaps direction-dependent, variations from their target values.

21.1.7.1.7. Symmetry

From the symmetry of the diffraction pattern, the point-group symmetry of the crystal lattice can usually be derived. It is important to merge the data in the point group with the highest possible symmetry (usually assessed using merging statistics) in order to minimize the chance of making an incorrect space-group assignment (Marsh, 1995, 1997; Kleywegt *et al.*, 1996). Once the first data set has been processed, it is always useful to compute a self-rotation function. A non-origin peak of comparable strength to the origin peak will indicate that the true space group has higher symmetry. [Similarly, a self-Patterson function can be calculated at this stage to detect any purely translational NCS (Kleywegt & Read, 1997).] Once the final model is available, a search for possibly missed higher symmetry can be carried out, *e.g.* using the method developed by Hooft *et al.* (1994).

Sometimes crystallographic symmetry breaks down (pseudo-symmetry): an apparent higher symmetry at low resolution does not hold at higher resolution. In some cases, this is a consequence of the chemistry of the system studied (*e.g.* an asymmetric ligand bound by a symmetric protein dimer). In other cases, it may go undetected and complicate space-group determination and solution and refinement of the structure.

When it comes to space-group determination, many of the lessons learned by small-molecule crystallographers also apply to macromolecular crystallography (Marsh, 1995; Watkin, 1996).

21.1.7.2. Model quality, coordinates

Many criteria (and computer programs) are available to check for structural outliers based only on analysis of Cartesian coordinate sets.

21.1.7.2.1. Geometry and stereochemistry

The covalent geometry of a model can be assessed by comparing bond lengths and angles to a library of 'ideal' values. In the past, every refinement and modelling program had its own set of 'ideal' values. This even made it possible to detect (with 95% accuracy) with which program a model had been refined, simply by inspecting its covalent geometry (Laskowski, Moss & Thornton, 1993). Nowadays, standard sets of ideal bond lengths and bond angles derived from an analysis of small-molecule crystal structures from the CSD (Allen *et al.*, 1979) are available for proteins (Engh & Huber, 1991; Priestle, 1994) and nucleic acids (Parkinson *et al.*, 1996). For other entities, typical bond lengths and bond angles can be taken from tables of standard values (Allen *et al.*, 1987) or derived by other means (Kleywegt & Jones, 1998; Greaves *et al.*, 1999).

For bond lengths, the r.m.s. deviation from ideal values is invariably quoted. Deviations from ideality of bond angles can be expressed directly as an angular r.m.s. deviation or in terms of angle distances (*i.e.* the angle $\angle ABC$ is measured by the 1–3 distance $|AC|$; note that this distance is also implicitly dependent on the bond lengths $|AB|$ and $|BC|$). There are some indications that protein geometry cannot always be captured by assuming unimodal distributions (*i.e.* geometric features with only a single 'ideal' value). For example, Karplus (1996) found that the main-chain bond angle τ_3 ($\angle$N—C$^\alpha$—C) varies as a function of the main-chain torsion angles φ and ψ.

Chirality is another important criterion in the case of biomacromolecules: most amino-acid residues will have the L configuration for their C$^\alpha$ atom. Also, the C$^\beta$ atoms of threonine and isoleucine residues are chiral centres (IUPAC–IUB Commission on Biochemical Nomenclature, 1970; Morris *et al.*, 1992). Chirality can be assessed in terms of improper torsion angles or chiral volumes. For example, to check if the C$^\alpha$ atom of any residue other than glycine has the L configuration, the improper (or virtual) torsion angle C$^\alpha$—N—C—C$^\beta$ should have a value of about +34° (a value near −34° would indicate a D-amino acid). The torsion angle is called improper or virtual because it measures a torsion around something other than a covalent bond, in this case the N—C 'virtual bond'. The chiral volume is defined as the triple scalar product of the vectors from a central atom to three attached atoms (Hendrickson, 1985). For instance, the chiral volume of a C$^\alpha$ atom is defined as

$$V_{C^\alpha} = (\mathbf{r}_{\rm N} - \mathbf{r}_{C^\alpha}) \cdot [(\mathbf{r}_{\rm C} - \mathbf{r}_{C^\alpha}) \times (\mathbf{r}_{C^\beta} - \mathbf{r}_{C^\alpha})],$$

where $\mathbf{r}_X$ is the position vector of atom X. It should be noted that the chiral volume also implicitly depends on the bond lengths and angles involving the four atoms.

Another issue to consider is that of moieties that are necessarily planar (*e.g.* carboxylate groups, phenyl rings; Hooft *et al.*, 1996*a*). Again, planarity can be assessed in two different ways: by inspecting a set of (possibly improper) torsion angles and calculating their r.m.s. deviation from ideal values (*e.g.* all ring torsions in a perfectly flat phenyl ring should be 0°) or by fitting a least-squares plane through each set of atoms and calculating the r.m.s. distance of the atoms to that plane. Note that for double bonds, *cis* and *trans* configurations cannot be distinguished by deviations from a least-squares plane, but they can be distinguished by an appropriately defined torsion angle.

21.1.7.2.2. Torsion angles (dihedrals)

The conformation of the backbone of every non-terminal amino-acid residue is determined by three torsion angles, traditionally called φ (C_{i-1}—N_i—C_i^α—C_i), ψ (N_i—C_i^α—C_i—N_{i+1}) and ω (C_i^α—C_i—N_{i+1}—C_{i+1}^α). Owing to the peptide bond's partial double-bond character, the ω angle is restrained to values near 0° (*cis*-peptide) and 180° (*trans*-peptide). *Cis*-peptides are relatively rare and usually (but not always) occur if the next residue is a proline (Ramachandran & Mitra, 1976; Stewart *et al.*, 1990). The average ω-value for *trans*-peptides is slightly less than 180° (MacArthur & Thornton, 1996), but surprisingly large deviations have been observed in atomic resolution structures (Sevcik *et al.*, 1996; Merritt *et al.*, 1998). The ω angle therefore offers little in the way of validation checks, although values in the range of ±20 to ±160° should be treated with caution in anything but very high resolution models. The φ and ψ torsion angles, on the other hand, are much less restricted, but it has been known for a long time that owing to steric hindrance there are several clearly preferred combinations of φ, ψ values (Ramakrishnan & Ramachandran, 1965). This is true even for proline and glycine residues, although their distributions are atypical (Morris *et al.*, 1992). Also, an overwhelming majority of residues that are not in regular secondary-structure elements are found to have favourable φ, ψ torsion-angle combinations (Swindells *et al.*, 1995). For these reasons, the Ramachandran plot (essentially a φ, ψ scatter plot) is an extremely useful indicator of model quality (Weaver *et al.*, 1990; Laskowski, MacArthur *et al.*, 1993; MacArthur & Thornton, 1996; Kleywegt & Jones, 1996*b*; Kleywegt, 1996; Hooft *et al.*, 1997). Residues that have unusual φ, ψ torsion-angle combinations should be scrutinized by the crystallographer. If they have convincing electron density, there is probably a good structural or functional reason for the protein to tolerate the energetic strain that is associated with the unusual conformation (Herzberg & Moult, 1991). As a rule, the residue types that are most often found as outliers are serine, threonine, asparagine, aspartic acid and histidine (Gunasekaran *et al.*, 1996; Karplus, 1996). The quality of a model's Ramachandran plot is most convincingly illustrated by a figure. Alternatively, the fraction of residues in certain predefined areas of the plot (*e.g.* core regions) can be quoted, but in that case it is important to indicate which definition of such areas was used. Sometimes, one may also encounter a Balasubramanian plot, which is a linear φ, ψ plot as a function of the residue number (Balasubramanian, 1977).

In protein structures, the plane of the peptide bond can have two different orientations (approximately related by a 180° rotation around the virtual $C^{\alpha}-C^{\alpha}$ bond) that are both compatible with a *trans* configuration of the peptide (Jones *et al.*, 1991). The correct orientation can usually be deduced from the density of the carbonyl O atom or from the geometric requirements of regular secondary-structure elements (in α-helices, all carbonyl O atoms point towards the C-terminus of the helix; in β-strands, carbonyl O atoms usually alternate their direction). In other cases, *e.g.* in loops with poor density, the correct orientation may be more difficult to determine and errors are easily made. By comparing the local C^{α} conformation to a database of well refined high-resolution structures, unusual peptide orientations can be identified and, if required, corrected (through a 'peptide flip'; Jones *et al.*, 1991; Kleywegt & Jones, 1997, 1998). Since flipping the peptide plane between residues i and $i + 1$ changes the ψ angle of residue i and the φ angle of residue $i + 1$ by ~180°, erroneous peptide orientations may also lead to outliers in the Ramachandran plot (Kleywegt, 1996; Kleywegt & Jones, 1998).

All amino-acid residues whose side chain extends beyond the C^{β} atom contain one or more conformational side-chain torsion angles, termed χ_1 ($N-C^{\alpha}-C^{\beta}-X^{\gamma}$, where X may be carbon, sulfur or oxygen, depending on the residue type; if there are two γ atoms, the χ_1 torsion is calculated with reference to the atom with the lowest numerical identifier, *e.g.* $O^{\gamma 1}$ for threonine residues), χ_2 ($C^{\alpha}-C^{\beta}-X^{\gamma}-X^{\delta}$) *etc.* Early on, it was found that the values that these torsion angles assume in proteins are similar to those expected on the basis of simple energy calculations and that in addition certain combinations of χ_1, χ_2 values are clearly preferred (so-called rotamer conformations; Janin *et al.*, 1978; James & Sielecki, 1983; Ponder & Richards, 1987). Analogous to Ramachandran plots, χ_1, χ_2 scatter plots can be produced that show how well a protein's side-chain conformations conform to known preferences (Laskowski, MacArthur *et al.*, 1993; Carson *et al.*, 1994). Alternatively, a score can be computed for each residue that shows how similar its side-chain conformation is to that of the most similar rotamer for that residue type. This score can be calculated as an r.m.s. distance between corresponding side-chain atoms (Jones *et al.*, 1991; Zou & Mowbray, 1994; Kleywegt & Jones, 1998) or it can be expressed as an r.m.s. deviation of side-chain torsion-angle values from those of the most similar rotamer (Noble *et al.*, 1993).

Other torsion angles that have been used for validation purposes include the proline φ torsion (restricted to values near −65° owing to the geometry of the pyrrolidine ring; Morris *et al.*, 1992) and the χ_3 torsion in disulfide bridges (defined by the atoms $C^{\beta}-S-S'-C^{\beta'}$ and restricted to values near +95 and −85°; Morris *et al.*, 1992). In addition to the torsion-angle values of individual residues, pooled standard deviations of χ_1 and/or χ_2 torsions have been used for validation purposes (Morris *et al.*, 1992; Laskowski, MacArthur *et al.*, 1993).

To assess the 'geometric strain' in a model on a per-residue basis, the refinement program *X-PLOR* (Brünger, 1992*b*) can produce geometric pseudo-energy plots. In such a plot, the ratio of $E_{\rm geom}(i)/{\rm r.m.s.}(E_{\rm geom})$ is calculated as a function of the residue number i. The pseudo-energy term $E_{\rm geom}$ consists of the sums of the geometric and stereochemical pseudo-energy terms of the force field ($E_{\rm geom} = E_{\rm bonds} + E_{\rm angles} + E_{\rm dihedrals} + E_{\rm impropers}$), involving only the atoms of each residue.

It has been observed that the more high-resolution protein structures become available, the more 'well behaved' proteins turn out to be, *i.e.* the distributions of conformational torsion angles and torsion-angle combinations become even tighter than observed previously and the numerical averages tend to shift somewhat (Ponder & Richards, 1987; Kleywegt & Jones, 1998; EU 3-D Validation Network, 1998; MacArthur & Thornton, 1999; Walther & Cohen, 1999).

21.1.7.2.3. C^{α}-only models

Validation of C^{α}-only models may be necessary if such a model is retrieved from the PDB to be used in molecular replacement or homology modelling exercises; however, not many validation tools can handle such models (Kleywegt, 1997). The C^{α} backbone can be characterized by $C^{\alpha}-C^{\alpha}$ distances (~2.9 Å for a *cis*-peptide and ~3.8 Å for a *trans*-peptide), $C^{\alpha}-C^{\alpha}-C^{\alpha}$ pseudo-angles and $C^{\alpha}-C^{\alpha}-C^{\alpha}-C^{\alpha}$ pseudo-torsion angles (Kleywegt, 1997). The pseudo-angles and torsion angles turn out to assume certain preferred value combinations (Oldfield & Hubbard, 1994), much like the backbone φ and ψ torsions, and this can be employed for the validation of C^{α}-only models (Kleywegt, 1997). In addition to these straightforward methods, the mean-field approach of Sippl (1993) is also applicable to C^{α}-only models.

21.1.7.2.4. Contacts and environments

Hydrophobic, electrostatic and hydrogen-bonding interactions are the main stabilizing forces of protein structure. This leads to packing arrangements where hydrophobic residues tend to interact with each other, where charged residues tend to be involved in salt links and where hydrophilic residues prefer to interact with each other or to point out into the bulk solvent. Serious model errors will often lead to violations of such simple rules of thumb and introduce non-physical interactions (*e.g.* a charged arginine residue located inside a hydrophobic pocket; Kleywegt *et al.*, 1996) that serve as good indicators of model errors. Directional atomic contact analysis (Vriend & Sander, 1993) is a method in which these empirical notions have been formalized through database analysis. For every group of atoms in a protein, it yields a score which in essence expresses how 'comfortable' that group is in its environment in the model under scrutiny (compared with the expectations derived from the database). If a region in a model (or the entire model) has consistently low scores, this is a very strong indication of model errors. The *ERRAT* program is based on the same principle, but it is less specific in that it assesses only six types of non-bonded interactions (CC, CN, CO, NN, NO and OO; Colovos & Yeates, 1993).

Hydrogen-bonding analysis can often be used to determine the correct orientation of asparagine, glutamine and histidine residues (McDonald & Thornton, 1995). Similarly, an investigation of unsatisfied hydrogen-bonding potential can be used for validation purposes (Hooft *et al.*, 1996*b*), as can calculation of hydrogen-bonding energies (Morris *et al.*, 1992; Laskowski, MacArthur *et al.*, 1993).

Finally, a model should not contain unusually short non-bonded contacts. Although most refinement programs will restrain atoms from approaching one another too closely, if any serious violations remain they are worth investigating, since they may signal an underlying problem (*e.g.* erroneous omission of a disulfide restraint or incorrect side-chain assignment).

21.1.7.2.5. Noncrystallographic symmetry

Molecules that are related by noncrystallographic symmetry exist in very similar, but not identical, physical environments. This implies that their structures are expected to be quite similar, although different relative domain orientations and local variations may occur (*e.g.* owing to different crystal-packing interactions; Kleywegt, 1996). Many criteria have been developed to quantify the differences between (NCS) related models. Some, such as the r.m.s. distance (*e.g.* on all atoms, backbone atoms or C^{α} atoms) are based on distances between equivalent atoms, measured after a (to some extent arbitrary; Kleywegt, 1996) structural superpositioning operation has been performed. Others are based on a comparison of torsion angles, be it of main-chain φ, ψ angles [*e.g.* $\Delta\varphi$, $\Delta\psi$ plot (Korn & Rose, 1994); multiple-model Ramachandran plot (Kleywegt, 1996); $\sigma(\varphi)$, $\sigma(\psi)$ plot (Kleywegt, 1996); circular variance (Allen & Johnson, 1991) plots of φ and ψ (G. J. Kleywegt, unpublished results); Euclidian φ, ψ distances (Carson *et al.*, 1994) or pseudo-energy values (Carson *et al.*, 1994)] or side-chain χ_1, χ_2 angles [*e.g.* multiple-model χ_1, χ_2 plot (Kleywegt, 1996); $\sigma(\chi_1)$, $\sigma(\chi_2)$ plots (Kleywegt, 1996); circular variance (Allen & Johnson, 1991) plots of χ_1 and χ_2 (G. J. Kleywegt, unpublished results); Euclidian χ_1, χ_2 distances (Carson *et al.*, 1994) or pseudo-energy values (Carson *et al.*, 1994)]. Still other methods are based on analysing differences in contact-surface areas (Abagyan & Totrov, 1997), temperature factors (Kleywegt, 1996) or the geometry of the C^{α} backbone alone (Flocco & Mowbray, 1995; Kleywegt, 1996). Many of these methods can also be used to compare the structures of related molecules in different crystals or crystal forms (*e.g.* complexes, mutants).

21.1.7.2.6. Solvent molecules

Solvent molecules provide an excellent means of 'absorbing' problems in both the experimental data and the atomic model. Neither their position nor their temperature factor are usually restrained (other than by the data and restraints that prevent close contacts) and sometimes even their occupancy is refined. At a resolution of ~2 Å, crystallographers tend to model roughly one water molecule for every amino-acid residue and at 1.0 Å resolution this number increases to ~1.6 (Carugo & Bordo, 1999). When waters are placed, it should be ascertained that they can actually form hydrogen bonds, be it to protein atoms or to other water molecules. Considering that several ions that are isoelectronic with water (Na^+, NH_4^+) are often used in crystallization solutions, one should keep in mind the possibility that some entities that have been modelled as water molecules could be something else (Kleywegt & Jones, 1997). A method to check if water molecules could actually be sodium ions, based on the surrounding atoms, has been published (Nayal & Di Cera, 1996).

21.1.7.2.7. Miscellaneous

Many other coordinate-based methods for assessing the validity or correctness of protein models have been developed. These include the profile method of Eisenberg and co-workers (Bowie *et al.*, 1991; Lüthy *et al.*, 1992), the inspection of atomic volumes (Pontius *et al.*, 1996), and the use of threading and other potentials (Sippl, 1993; Melo & Feytmans, 1998; Maiorov & Abagyan, 1998). Some of these methods are described in more detail elsewhere in this volume. The program *WHAT IF* (Vriend, 1990) contains a large array of quality checks, many of which are not available in other programs, that span the spectrum from administrative checks to global quality indicators (Hooft *et al.*, 1996). During the refinement process, coordinate shifts can be used as a rough indication of 'quality' or, rather, convergence (Carson *et al.*, 1994; Kleywegt & Jones, 1996*a*). Crude models tend to undergo much larger changes during refinement than models that are essentially correct and complete. Also at the residue level, large coordinate shifts indicate residues that are worth a closer look.

Laskowski *et al.* (1994) have formulated single-number geometrical quality criteria, which they dubbed '*G* factors' in analogy to crystallographic *R* values. These *G* factors combine the results of a number of quality checks (covalent geometry, main-chain and side-chain torsion angles *etc.*) in a single number.

21.1.7.3. Model quality, temperature factors

In crystallographic refinement, atomic displacement parameters (ADPs; often referred to as temperature factors or *B* factors) model the effects of static and dynamic disorder. Except at high resolution (typically better than 1.5 Å), where there are sufficient observations to warrant refinement of anisotropic temperature factors, ADPs are usually constrained to be isotropic. The isotropic temperature factor *B* of an atom is related to the atom's mean-square displacement $\langle \Delta r^2 \rangle$ according to $B = 8\pi^2 \langle \Delta r^2 \rangle / 3$. Compared with the atomic coordinates, there are usually comparatively few restraints on temperature factors during refinement. Therefore, particularly at low resolution, temperature factors often function as 'error sinks' (Read, 1990). They absorb not only the effects of static and dynamic disorder, but also of various kinds of model errors.

Compared with the wealth of statistics that can be used to check and validate coordinates, there are relatively few methods available to assess how reasonable a model's temperature factors are. One obvious check is to see how well the average temperature factor of the model matches the value calculated from the data, using either a Wilson plot (Wilson, 1949) or the Patterson origin peak (Vaguine *et al.*, 1999). Since the average temperature factor of a model is usually not restrained, this is a useful check that has been used on several occasions to justify high average *B* factors. One should keep in mind that a low average *B* factor, *per se*, is not necessarily an indication of high model quality. For instance, a backwards-traced protein model can have a considerably lower average *B* factor than a correct model at a similar resolution (Kleywegt & Jones, 1995*b*). Average (and minimum and maximum) temperature-factor values can also be listed separately for various groups of atoms (*e.g.* individual protein or nucleic acid molecules, ligands, solvent molecules). A simple plot of residue-averaged temperature factors as a function of residue number may reveal regions of the molecule that have consistently high *B* factors, which may be a consequence of problems in the model (Kleywegt *et al.*, 1996).

Other statistics pertain to the r.m.s. differences in *B* factors between atoms that are somehow related, for example through a chemical bond (r.m.s. ΔB_{bonded}), through a 1–3 interaction or through noncrystallographic symmetry (possibly after correcting for any differences between the average B factors of the NCS-related molecules). Sometimes these statistics are calculated separately for main-chain and side-chain atoms. If the B factors of such related atoms have been restrained to be similar during refinement, these checks do not provide a convincing indication of the quality of the model. On the other hand, the B factors of atoms that have non-bonded interactions are usually not restrained to be similar, which renders the r.m.s. B-factor difference between such atoms (r.m.s. $\Delta B_{\text{non-bonded}}$) slightly more informative.

Since proteins tend to consist of a tightly packed core with more flexible regions at the surface, a radial B-factor plot (*i.e.* a plot of the average B factor of all atoms in a certain distance range from the centre of the molecule as a function of the distance) is expected to be shaped roughly like a half-parabola. Kuriyan & Weis (1991) used a ten-parameter isotropic rigid-molecule model of the mean-square atomic displacement (Schomaker & Trueblood, 1968). After obtaining values for the ten parameters (either by refinement against the structure-factor data or by fitting to the refined B factors of the model), the B factor of any atom can be calculated and depends only on its coordinates. They found that regions with large discrepancies between the refined and fitted B factors tend to be associated with errors or problems in a model.

Validation of anisotropic ADPs (Merritt, 1999), non-unit occupancies and H atoms, all of which are usually associated with high-resolution data, is still in its infancy. The validity of modelling anisotropic ADPs can be assessed by comparing the reduction of the conventional and free R values. If occupancies are used for multiple conformations of, for example, a side chain, the sum of the occupancies should be unity.

21.1.7.4. Model versus experimental data

21.1.7.4.1. R values

The traditional statistic used to assess how well a model fits the experimental data is the crystallographic R value,

$$R = \sum w \big| |F_o| - k|F_c| \big| / \sum |F_o|.$$

This statistic is closely related to the standard least-squares crystallographic residual $\sum w(|F_o| - k|F_c|)^2$ and its value can be reduced essentially arbitrarily by increasing the number of parameters used to describe the model (*e.g.* by refining anisotropic ADPs and occupancies for all atoms) or, conversely, by reducing the number of experimental observations (*e.g.* through resolution and σ cutoffs) or the number of restraints imposed on the model. Therefore, the conventional R value is only meaningful if the number of experimental observations and restraints greatly exceeds the number of model parameters. In 1992, Brünger introduced the free R value (R_{free}; Brünger, 1992*a*, 1993, 1997; Kleywegt & Brünger, 1996), whose definition is identical to that of the conventional R value, except that the free R value is calculated for a small subset of reflections that are not used in the refinement of the model. The free R value, therefore, measures how well the model predicts experimental observations that are not used to fit the model (cross-validation). Until a few years ago, a conventional R value below 0.25 was generally considered to be a sign that a model was essentially correct (Brändén & Jones, 1990). While this is probably true at high resolution, it was subsequently shown for several intentionally mistraced models that these can be refined to deceptively low conventional R values (Jones *et al.*, 1991; Kleywegt & Jones, 1995*b*; Kleywegt & Brünger, 1996). Brünger suggests a threshold value of 0.40 for the free R value, *i.e.* models with free R values greater than 0.40 should be treated with caution (Brünger, 1997). Tickle and coworkers have developed methods to estimate the expected value of R_{free} in least-squares refinement (Tickle *et al.*, 1998). Since the difference between the conventional and free R value is partly a measure of the extent to which the model over-fits the data (*i.e.* some aspects of the model improve the conventional but not the free R value and are therefore likely to fit noise rather than signal in the data), this difference $R_{\text{free}} - R$ should be small (Kleywegt & Jones, 1995*a*; Kleywegt & Brünger, 1996). Alternatively, the R_{free} ratio (defined as R_{free}/R; Tickle *et al.*, 1998) should be close to unity. Various practical aspects of the use of the free R value have been discussed by Kleywegt & Brünger (1996) and by Brünger (1997).

Self-validation is an alternative to cross-validation and in the case of crystallographic refinement, the Hamilton test (Hamilton, 1965) is a prime example of this. This method enables one to assess whether a reduction in the R value is statistically significant given the increase in the number of degrees of freedom. Application of this test in the case of macromolecules is compounded by the difficulty of estimating the effect of the combined set of restraints on the (effective) number of degrees of freedom, but some information can nevertheless be gained from such an analysis (Bacchi *et al.*, 1996).

21.1.7.4.2. Real-space fits

The fit of a model to the data can also be assessed in real space, which has the advantage that it can be performed for arbitrary sets of atoms (*e.g.* for every residue separately). Jones *et al.* (1991) introduced the real-space R value, which measures the similarity of a map calculated directly from the model (ρ_c) and one which incorporates experimental data (ρ_o) as

$$R = \sum |\rho_o - \rho_c| / \sum |\rho_o + \rho_c|,$$

where the sums extend over all grid points in the map that surround the selected set of atoms. The real-space fit can also be expressed as a correlation coefficient (Jones & Kjeldgaard, 1997), which has the advantage that no scaling of the two densities is necessary. Chapman (1995) described a modification in which the density calculated from the model is derived by Fourier transformation of resolution-truncated atomic scattering factors.

The program *SFCHECK* (Vaguine *et al.*, 1999) implements several variations on the real-space fit. The normalized average displacement measures the tendency of groups of atoms to move away from their current position. The density correlation is a modification of the real-space correlation coefficient. The residue-density index is calculated as the geometric mean of the density values of a set of atoms, divided by the average density of all atoms in the model. It therefore measures how high the electron-density level is for the set of atoms considered (*e.g.* all side-chain atoms of a residue). The connectivity index is identical to the residue-density index, but is calculated only for the N, C^{α} and C atoms. It thus provides an indication of the continuity of the main-chain electron density.

21.1.7.4.3. Coordinate error estimates

Since a measurement without an error estimate is not a measurement, crystallographers are keen to assess the estimated errors in the atomic coordinates and, by extension, in the atomic positions, bond lengths *etc.* In principle, upon convergence of a least-squares refinement, the variances and covariances of the model parameters (coordinates, ADPs and occupancies) may be obtained through inversion of the least-squares full matrix

(Sheldrick, 1996; Ten Eyck, 1996; Cruickshank, 1999). In practice, however, this is seldom performed as the matrix inversion requires enormous computational resources. Therefore, one of a battery of (sometimes quasi-empirical) approximations is usually employed.

For a long time, the elegant method of Luzzati (1952) has been used for a different purpose (namely, to estimate average coordinate errors of macromolecular models) than that for which it was developed (namely, to estimate the positional changes required to reach a zero R value, using several assumptions that are not valid for macromolecules; Cruickshank, 1999). A Luzzati plot is a plot of R value *versus* $2\sin\theta/\lambda$, and a comparison with theoretical curves is used to estimate the average positional error. Considering the problems with conventional R values (discussed in Section 21.1.7.4.1), Kleywegt *et al.* (1994) instead plotted free R values to obtain a cross-validated error estimate. This intuitive modification turned out to yield fairly reasonable values in practice (Kleywegt & Brünger, 1996; Brünger, 1997). Read (1986, 1990) estimated coordinate error from σ_A plots; the cross-validated modification of this method also yields reasonable error estimates (Brünger, 1997).

Cruickshank, almost 50 years after his work on the precision of small-molecule crystal structures (Cruickshank, 1949), introduced the diffraction-component precision index (DPI; Dodson *et al.*, 1996; Cruickshank, 1999) to estimate the coordinate or positional error of an atom with a B factor equal to the average B factor of the whole structure. In several cases for which full-matrix error estimates are available, the DPI gives quantitatively similar results. *SFCHECK* (Vaguine *et al.*, 1999) calculates both the DPI and Cruickshank's 1949 statistic (now termed the 'expected maximal error') based on the slope and the curvature of the electron-density map.

21.1.7.4.4. Noncrystallographic symmetry

Despite the multitude of criteria for assessing conformational differences between related molecules, there was until recently no objective way to assess whether such differences were a true reflection of the experimental data or a manifestation of refinement artifacts (Kleywegt & Jones, 1995*b*; Kleywegt, 1996). However, it has been found that electron-density maps calculated with experimental phases (or, at least, phases that are biased as little as possible by the model) and amplitudes can be used to correlate expected similarities (based on the data) with observed ones (manifest in the final refined models; Kleywegt, 1999). This method uses a local density-correlation map, as introduced by Read (Vellieux *et al.*, 1995), to measure the local similarity of the density of two or more models on a per-atom or per-residue basis. By comparing these values to the observed structural differences in the final models, it is relatively easy to check if the latter differences are warranted by the information contained in the experimental data (Kleywegt, 1999).

21.1.7.4.5. Difference density quality

van den Akker & Hol (1999) described a method (called *DDQ*, standing for difference density quality) to assess the local and global quality of a model based on analysis of an $(F_o - F_c, \alpha_c)$ map calculated after omission of all water molecules. In this method, the map and model are used to calculate several scores. One score assesses the presence or absence of favourably positioned water peaks near polar and apolar atoms. Other scores provide a measure for the presence or absence of positive and negative shift peaks that may indicate incorrect coordinates, temperature factors or occupancies. The scores can be averaged per residue or for an entire model and can be used to detect problems in models. The method appears to be applicable to ~3 Å resolution.

21.1.7.5. Accountancy

The opinions as to what constitutes an error in a model vary somewhat in the community [compare Hooft *et al.* (1996) and Jones *et al.* (1996), for instance], but most people would agree that a crystallographic error is one that requires access to the experimental data for its verification, and whose correction alters the calculated structure factors (*e.g.* position, B factor, occupancy or scattering factors of one or more atoms). In addition to this, there are nomenclature rules and conventions to which a model that is made publicly available should adhere. Separate from this is the issue of the (more clerical) validation of public database entries ('PDB files'; Hooft *et al.*, 1994, 1996) which, while important to maintain the integrity of these databases, ultimately ought to be the responsibility of the database curators (Jones *et al.*, 1996; Keller *et al.*, 1998; Abola *et al.*, 2000).

21.1.8. Future

During the 1990s, the field of protein model validation matured rapidly (MacArthur *et al.*, 1994; EU 3-D Validation Network, 1998; Laskowski *et al.*, 1998) and further fundamental breakthroughs seem unlikely at present (although it would be highly desirable to be able to calculate and compare the information content of experimental data and models alike). In contrast, work on the validation of nucleic acid models (Schultze & Feigon, 1997) and hetero-entities (Kleywegt & Jones, 1998) has only just begun. In addition, there is still scope for further development of validation methods that use both the atomic model and the crystallographic data. In addition, the increasing number of structures that are solved at (near-)atomic resolution may lead to an adjustment of some validation criteria, *e.g.* of 'ideal' geometric target values, rotamer libraries *etc.* Also, validation of model aspects typically associated with very high resolution studies (refined occupancies, alternative conformations, anisotropic ADPs, H atoms) is still poorly developed. An increased understanding and appreciation of factors that determine model quality (and knowledge of how to measure them) will be important for the development of more automatic methods for protein structure determination. This in turn will enable 'black-box' high-throughput protein crystallography to become a reality, at least for 'run-of-the-mill' structures.

The author gratefully acknowledges the many useful discussions about validation with Alwyn Jones (Uppsala), Axel Brunger (Yale), Eleanor Dodson (York), Randy Read (Cambridge), Carl-Ivar Brändén (Stockholm), the members of the EU-funded 3-D Validation Network and many other colleagues in the field. This work was supported by the Swedish Foundation for Strategic Research (SSF), its Structural Biology Network (SBNet) and the EU-funded 3-D Validation Network.

Chapter 21.2. Assessing the quality of macromolecular structures

S. J. Wodak, A. A. Vagin, J. Richelle, U. Das, J. Pontius and H. M. Berman

21.2.1. Introduction

X-ray crystallography and nuclear magnetic resonance (NMR) spectroscopy are the two major techniques that provide detailed information on the atomic structure of macromolecules. Usually, however, the data obtained from these techniques are not of high enough resolution to define the atomic positions of a macromolecule with sufficient precision. Deriving the atomic models from the experimental data therefore involves sophisticated optimization (refinement) procedures, in which constraints based on prior knowledge about the chemical structure of the molecule and its conformational properties are applied. The resulting models are therefore prone to errors, which fall into two broad categories: systematic errors caused by biases during the structure determination and refinement procedures, and random errors which affect the precision of the model. Moreover, the quality of the model can vary in different regions of the structure, often due to higher local conformational or thermal disorder in certain parts.

With the rapid growth in the number of structures of macromolecules determined and the spreading use of structural information in different areas of science, the availability of objective criteria and methods for evaluating the quality of these structures has become a very important requirement.

A variety of validation procedures have been proposed by many groups (for recent reviews, see MacArthur *et al.*, 1994, and Laskowski *et al.*, 1998). The procedures involve two main approaches. One approach comprises procedures that validate the geometric and conformational parameters of the final model. This is done by measuring the extent to which the parameters deviate from standard values, derived from crystals of small molecules or from a set of high-quality structures of other macromolecules. The main limitation of this approach is that the quality of a model is defined by comparison with other known models without taking into account the experimental data. This harbours the danger of considering unusual conformations related to biological function as errors in the model or of accepting as 'normal' only what has already been observed before. The second and most important approach by far comprises procedures that take into account the experimental data and evaluate the agreement of the atomic model with these data. These procedures can, in principle, evaluate systematic errors and biases that affect the global quality of the model and can also detect local imprecision. The most commonly cited measures of agreement between the model as a whole and the data are the R factor and the 'free R factor', R_{free}. Criteria for evaluating the local agreement of the model with electron density on a per-atom or per-residue basis are also available, and, more recently, access to more powerful computers has made it possible to compute the standard uncertainties of individual parameters, such as atomic coordinates or thermal factors.

Finally, the growing number of atomic resolution structures – primarily of proteins – is starting to provide a valuable source of much more precise information about the structures' geometrical and conformational properties. This should contribute to the improvement of standard values used in validation.

In this chapter, we present an overview of the different types of validation procedures applied to proteins and nucleic acids. We illustrate, in some detail, an approach to model validation based on atomic volumes embodied in the program *PROVE* and describe the package *SFCHECK*, which combines a set of criteria for evaluating the quality of the experimental data and the agreement of the model with the data.

21.2.2. Validating the geometric and stereochemical parameters of the model

21.2.2.1. Comparisons against standard values derived from crystals of small molecules

This concerns the validation of the covalent geometry of the atomic model. It involves comparing the bond distances and angles of the macromolecule against standard values and their associated uncertainties, derived from crystal structures of small organic molecules available in the Cambridge Structural Database, CSD (Allen *et al.*, 1979, 1983).

The standard values derived in this way are also used as restraints in crystallographic refinement programs, such as *XPLOR* (Brünger, 1992*a*) or the *CCP*4 suite of programs (Collaborative Computational Project, Number 4, 1994). As a result, the bond distances and angles of the final model usually agree well with their standard values, and the degree of scatter merely reflects the relative weight imposed on the various terms of the target function during refinement.

For proteins, the most commonly used standard values for the bond distances and angles are those compiled by Engh & Huber (1991) from molecular fragments in the CSD that most closely resemble chemical groups in amino acids. These parameters were shown to yield an improved description over that provided by the param19x.pro used in *XPLOR*, especially for the covalent geometry of aromatic rings in side-chain groups. It is noteworthy that these CSD-derived bond distances and angles can differ significantly from those used in molecular dynamics force fields, such as that of a recent version of *CHARMM* (MacKerell *et al.*, 1998). In these force fields, covalent-geometry parameters are obtained by a different strategy. They are optimized together with non-bonded parameters against a large body of available energy and structural data for a limited set of compounds representing amino-acid building blocks.

Protein-structure validation packages, such as *PROCHECK* (Laskowski *et al.*, 1993) and *WHAT IF* (Hooft, Vriend *et al.*, 1996), flag all bond distances and angles that deviate significantly from the database-derived reference values. This includes analysis of the deviations from planarity in aromatic rings and planar side-chain groups.

Similar checks are performed for the covalent geometry of atomic models of RNA or DNA oligo- and polynucleotides. Here, standard ranges for bond distances and angles are derived from crystal structures of nucleic acid bases, mononucleosides and mononucleotides in the CSD (Clowney *et al.*, 1996; Gelbin *et al.*, 1996). These values are used in validation procedures developed

Copyright © 2012 International Union of Crystallography

by the Nucleic Acid Database (NDB) (Berman *et al.*, 1992) and in crystallographic refinement programs. For higher-resolution structures (better than 2.4 Å), a standard geometry, dependent on the sugar pucker conformation (C2′ *endo* or C3′ *endo*) (Parkinson *et al.*, 1996), is used.

Validation of the covalent geometry of the so-called 'hetero groups' (chemically modified monomer groups or small molecules that bind to macromolecules) is much more difficult. It therefore tends not to be routinely performed, and, as a result, the quality of the hetero groups in the models deposited in the Protein Data Bank (PDB) (Bernstein *et al.*, 1977; Berman *et al.*, 2000) varies widely.

The variety of the chemical structures of these molecules (the current release of the PDB contains about 2700 chemically distinct compounds) makes it difficult to archive them consistently, let alone to compile the dictionaries containing the required reference values in advance. Proper handling and verification of such groups require a comprehensive and rigorous description of the chemical components, as well as flexible means of deriving the appropriate reference geometries.

The development of systematic procedures for checking bond lengths and various torsion angles of hetero groups (Kleywegt & Jones, 1998) is a step in the right direction. Further progress should come, thanks in part to the recently adopted macromolecular Crystallographic Information File (mmCIF) format (Bourne *et al.*, 1997), which provides the necessary framework for a much more comprehensive and rigorous description of the molecular components. Using this description as the basis, automated tools for building 'customized' dictionaries of geometrical standards have been developed. One such tool is A LigAnd and Monomer Object Data Environment (*A LA MODE*) (Clowney *et al.*, 1999). It starts from a minimal topological description of a ligand or monomer component and performs the tasks required to construct the mmCIF component description. This includes querying the CSD, integration and book-keeping of database survey results, analysis and comparison of covalent geometry and stereochemistry, and the assembly of complex model structures from the results of multiple database surveys. Tools such as this considerably simplify the handling of small molecules at the refinement, validation and archiving stages.

21.2.2.2. *Comparisons against standard values derived from surveys of other macromolecules*

This involves computing a number of stereochemical, geometric and energy parameters from the atomic coordinates of the macromolecule and comparing them with standard ranges derived from high-quality crystal structures of other macromolecules. These standards represent the 'expected' properties, and the aim is to evaluate the quality of a model by measuring the extent to which it departs from these properties.

This evaluation is usually performed at the global level, in order to assess the quality of the structure as a whole, and on the local level, to identify specific regions with unusual properties. Such regions may represent genuine problems with the model or unusual conformations adopted for functional purposes, and it is sometimes difficult to distinguish between these two alternatives. The choice of reference structures from which the standards are derived is a crucial aspect of the approach, since both the mean and shape of the reference distributions may be affected by it.

21.2.2.2.1. *Validation of stereochemical and non-bonded parameters*

Morris *et al.* (1992) pioneered this type of validation for proteins. The software *PROCHECK* (Laskowski *et al.*, 1993), which implements and extends this approach, is described in detail in Chapter 21.4 of this volume. A very important evaluation criterion is the Ramachandran-plot quality, where the distribution of the backbone φ, ψ angles of a given protein structure is compared to that in high-quality structures. The comparison is performed both globally, by determining the proportion of the residues in favourable (core) regions of the plot, and locally, by the log-odds (G-factor) value, which measures how normal or unusual a residue's location is in the plot for a given residue type.

A similar strategy is used to evaluate other stereochemical parameters, such as the side-chain torsion angles (χ_1, χ_2, χ_3 *etc.*), the peptide bond torsion (ω), the C^α tetrahedral distortion, disulfide bond geometry and stereochemistry.

An evaluation of the backbone hydrogen-bonding energy is also performed, using the Kabsch & Sander (1983) algorithm, by comparison with distributions computed from high-resolution protein structures.

Other programs like *WHAT IF* (Hooft, Vriend *et al.*, 1996) perform similar evaluations. This program computes the expected φ, ψ distribution for each residue type from a data set of non-redundant high-quality structures and evaluates how the φ, ψ distribution of a given protein deviates from the expected values (Hooft *et al.*, 1997). A somewhat different version of this approach is proposed by Kleywegt & Jones (1996). *WHAT IF* also computes other quality indicators such as the number of buried unsatisfied hydrogen bonds or the extent of the overlap of van der Waals spheres ('clashes'). In addition, it verifies the orientation of His, Gln and Asn side chains, based on a hydrogen-bond network analysis, which also takes into account hydrogen bonds between symmetry-related molecules (Hooft, Sander & Vriend, 1996).

The very small fraction of structures (< 1.3%) for which only the C^α coordinates are deposited cannot be validated by the standard techniques. For these structures, two sets of parameters were shown to be useful (Kleywegt & Jones, 1996). They are the $C^\alpha - C^\alpha$ distances and a Ramachandran-like plot which displays for each residue the $C^\alpha_{i-1} - C^\alpha_i - C^\alpha_{i+1} - C^\alpha_{i+2}$ dihedral angle against the $C^\alpha_{i-1} - C^\alpha_i - C^\alpha_{i+1}$ angle. Deviations from the expected distributions of these parameters, computed from a set of high-quality complete protein structures, are used as quality indicators.

The validation of nucleic acid stereochemistry, in particular DNA, has a much shorter history. Only in recent years has the number of high-quality nucleic acid crystal structures become large enough to permit the derivation of reliable conformational trends. Schneider *et al.* (1997) derived ranges and mean values for the torsion angles of the sugar–phosphate backbone in helical DNA from a set of 96 oligodeoxynucleotide crystal structures. These ranges form the basis for the nucleic acid structure validation protocols currently implemented at the NDB.

21.2.2.2.2. *Validation using knowledge-based interaction potentials and profiles*

These methods represent a distinct set of approaches to the validation of the non-bonded and conformational parameters of the model. They involve computing the relative frequencies of residue–residue or atom–atom contacts from a set of high-quality protein structures and evaluating how the contacts in a given protein deviate from these standard frequencies. Most often, these frequencies are translated into potentials (energies) using the Boltzmann relation (Sippl, 1990), and these 'knowledge-based' potentials are used to score the structure (for a review, see Wodak & Rooman, 1993). The potentials that consider residue–residue interactions, as in the software *PROSA II* (Sippl, 1993), are usually quite crude since each residue is represented by a single interaction centre. They can therefore detect only gross errors in chain tracing or identify incorrectly modelled segments in an otherwise correct structure, but can not validate detailed atomic positions. The same limitation applies to procedures based on three-dimensional (3D) environment profiles (Eisenberg *et al.*, 1997). The latter consider the relative frequencies of finding each of the 20 amino acids in a given local 3D environment defined by the residue buried area, the ratio of polar *versus* non-polar neighbours and the secondary structure. The corresponding energies are used to score the compatibility of a structure with its amino-acid sequence in a manner similar to the residue–residue interaction potentials.

Finally, validation procedures based on the relative frequencies of atom–atom interactions in known protein structures have also been developed (Melo & Feytmans, 1997, 1998). These methods, consolidated in the software *ANOLEA*, are capable of identifying local errors and problems of sequence misalignment in protein structures built by homology modelling. In addition, energy Z scores computed with these potentials for whole protein structures correlate well with the resolution of the X-ray data, as shown below for the volume-based Z scores.

21.2.2.2.3. Deviations from standard atomic volumes as a quality measure for protein crystal structures

The observations that protein X-ray structures are at least as tightly packed as small-molecule crystals (Richards, 1974; Harpaz *et al.*, 1994) and that the packing density inside proteins displays very limited variation (Richards, 1974; Finney, 1975) suggest that atomic volumes or measures of atomic packing can be added to the list of parameters for assessing the quality of protein structures.

Packing and related measures have been used to compare structures of proteins derived by both X-ray diffraction and NMR spectroscopy. Ratnaparkhi *et al.* (1998) analysed pairs of protein structures for which both crystal and NMR structures were available. They found that the packing values of the NMR models displayed a much larger scatter than those of the corresponding crystal structures, suggesting that this is probably due to the fact that accurate values of the packing density cannot, at present, be obtained from NMR data. Similar conclusions were reached using measures of residue–residue contact area (Abagyan & Totrov, 1997).

Here, we describe the approach of Pontius *et al.* (1996), in which deviations from standard atomic volumes are used to assess the quality of a protein model, both overall and in specific regions.

The volumes occupied by atoms and residues inside proteins can be readily computed using the Voronoi method (Voronoi, 1908), first applied to proteins by Richards (1974) and Finney (1975). This method uses the atomic positions of the molecular model, and the volume assigned to each atom is defined as the smallest polyhedron created by the set of planes bisecting the lines joining the atom centre to those of its neighbours (Fig. 21.2.2.1).

The use of the classical Voronoi procedure is justified in the context of validation because it avoids the need to derive a consistent set of van der Waals radii for atoms in the system. Such sets are used by other volume-calculation methods in order to partition space more accurately (Richards, 1974, 1985; Gellatly & Finney, 1982). Assigning a consistent set of radii to protein atoms is, indeed, not straightforward due to the heterogeneity of the interactions within the protein (polar, ionic, non-polar) and the presence of a large variety of hetero groups.

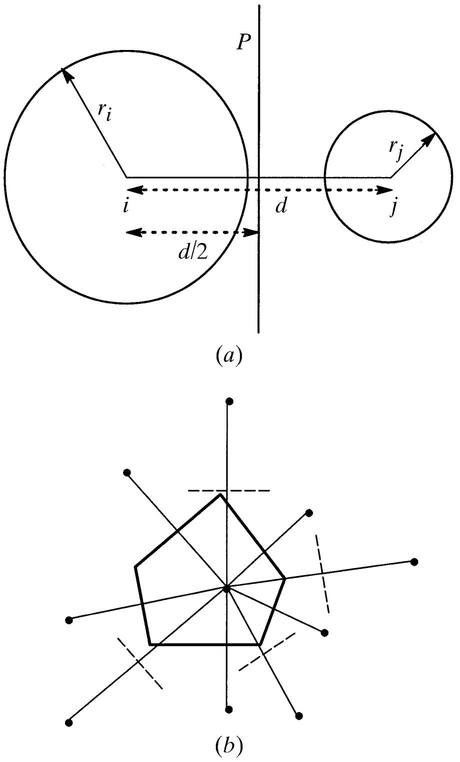

Figure 21.2.2.1
The Voronoi polyhedron. (*a*) Positioning of the dividing plane P between two atoms i and j, with van der Waals radii r_i and r_j, respectively, separated by a distance d. The plane P is positioned at $d/2$. (*b*) 2D representation of the Voronoi polyhedron of the central atom. This polyhedron is the smallest polyhedron delimited by all the dividing planes of the atom.

Structure-quality assessment based on volume calculations involves computing the atomic volumes in a subset of highly resolved and refined protein structures and analysing the distributions of these volumes for different atomic types, defined according to their chemical nature and bonded environment. These distributions define the expected ranges (mean and standard deviation) for the volume of each category of atoms. Atomic volumes in a given structure are then compared to the expected ranges, and statistically significant deviations from these ranges are flagged.

The program *PROVE* (Pontius *et al.*, 1996) implements such an approach using the analytic algorithms for volume and surface-area calculations encoded in *SurVol* (Alard, 1991). It computes for each atom i in a structure its volume Z score ($Z \text{ score} = \left|V_i^k - \overline{V^k}\right| / \sigma^k$), where the superscript k designates the particular atom type (*e.g.*, the C^α atom in a Leu residue), and $\overline{V^k}$ and σ^k are, respectively, the mean and standard deviation of the reference volume distribution for the corresponding atom type. These reference distributions are derived from a set of high-quality protein crystal structures using exactly the same calculation procedure (Pontius *et al.*, 1996).

Atoms with absolute Z scores > 3 are flagged as possible problem regions in the protein model, and residues containing such atoms are highlighted on graphical plots of the same type as those used by the *PROCHECK* program and on molecular

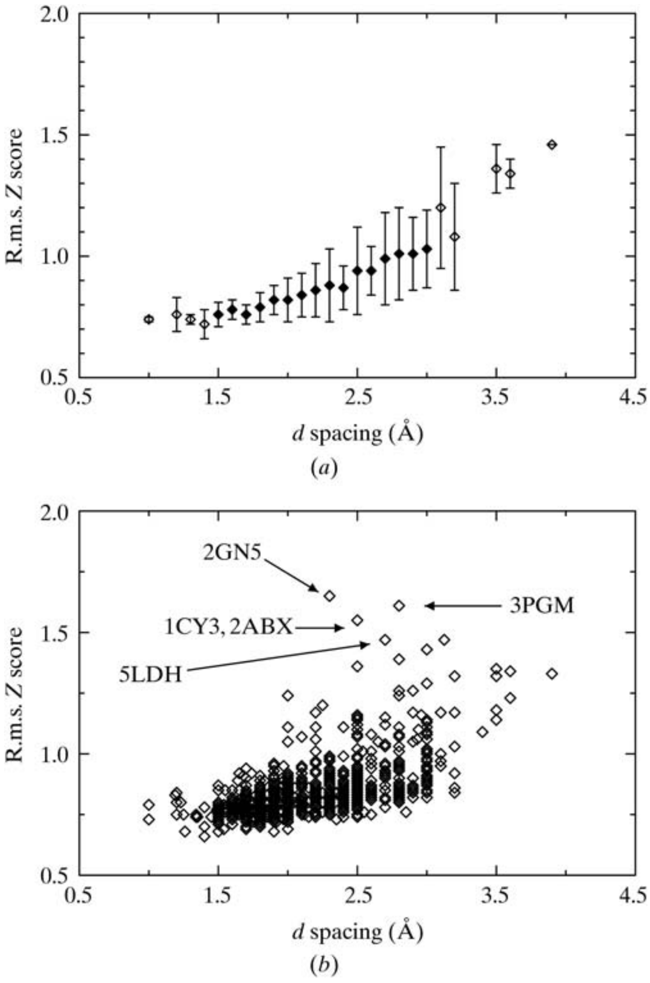

Figure 21.2.2.2
Atomic volume Z score r.m.s. variation with nominal resolution (d spacing) in 900 protein structures from the PDB. (*a*) Average of the r.m.s. volume Z score computed for structures having the same resolution (to within ±0.1 Å). The vertical bars indicate the magnitude of the standard deviations of the r.m.s. volume Z score in individual d-spacing bins. Graph points are derived from less than 10 structures (open diamonds) and from more than 10 structures (filled diamonds). (*b*) R.m.s. Z-score values as in (*a*), displayed for individual structures as a function of resolution. The five furthest outlier proteins are marked by their PDB codes.

models displayed using programs such as *Rasmol* (Sayle & Milner-White, 1995).

In addition to the validation of the local quality of the model, its overall quality can be assessed by the *root-mean-square volume Z score* of all its atoms (see Fig. 21.2.2.2 for definition). As for many stereochemical global quality indicators, this Z score shows good correlation with the nominal resolution (d spacing) of the crystallographic data, as illustrated in Fig. 21.2.2.2(*a*). This figure also shows that Z-score ranges can be defined for each resolution interval. The Z scores of individual proteins that lie outside these intervals may be indicative of 'problem' structures. This is clearly the case for the two proteins 2ABX and 2GN5, whose Z scores are much higher than average (Fig. 21.2.2.2*b*).

Since the Voronoi volume of solvent-accessible atoms cannot be defined, because these atoms are not completely surrounded by other atoms, only completely buried atoms are scored.

The current version of *PROVE* is unable to measure the deviations from standard volumes for atoms in nucleic acids or hetero groups, simply because of the lack of reference volumes for these structures. This should change in the near future, at least for nucleic acids, thanks to the growing number of high-quality nucleic acid crystal structures from which standard volume ranges could be readily derived.

21.2.3. Validation of a model *versus* experimental data

By far the most important measure of the quality of a given atomic model is its agreement with the experimental data. This type of validation is geared towards detecting systematic errors, which determine the overall accuracy of the model, and random errors, which affect the precision of the model.

Systematic errors are difficult to detect even in highly refined structures, especially at lower resolution. The most commonly used measures of the agreement between the atomic coordinates and the X-ray data are the classical R factor and the 'free R factor' ($R_{\rm free}$) (Brünger, 1992*b*). The latter is based on standard statistical cross-validation techniques (Brünger, 1997) and is therefore less amenable to manipulation, such as leaving out weak data or over-fitting the data with too many parameters. Currently, nearly half of the publications on macromolecular structures report $R_{\rm free}$ values, an indication that its use is becoming more widespread. So far, however, there are no clear guidelines indicating what an 'acceptable' $R_{\rm free}$ value should be (Kleywegt & Brünger, 1996).

An expression for estimating the expected $R_{\rm free}$ value has been proposed (see Dodson *et al.*, 1996) and used to assess the significance of the drop in $R_{\rm free}$ during refinement. Accurate expressions for the expected ratio of $R_{\rm free}$ to R (the $R_{\rm free}$ ratio) have also been derived theoretically (Tickle *et al.*, 1998). This ratio seems to be independent of random errors and can be used to detect systematic errors at the convergence of the least-squares refinement. The remaining problem is to determine what the precision of $R_{\rm free}$ or the $R_{\rm free}$ ratio should be. In other words, if the $R_{\rm free}$ ratio differs from the expected value, when is the difference significant? This requires knowing the variance of these parameters. Estimating the precision of $R_{\rm free}$ can be done empirically by performing repeated refinements of the same structure with different sets of reflections removed (Brünger, 1997). From such analysis, a useful approximation to the $R_{\rm free}$ precision was suggested to be the ratio $R_{\rm free}/(n)^{1/2}$, where n is the number of reflections in the test set.

Evaluating the precision of the refined parameters, that is, the atomic coordinates and the temperature or B factors, is a different matter. In small-molecule crystallography, the standard uncertainty (s.u.) of the parameters can be computed from the variance–covariance matrix, obtained by inverting the full normal-equations matrix (Cruickshank, 1965). This can, in principle, also be done for the parameters of macromolecules. However, the number of second derivatives to be computed and the size of the matrix to be inverted are so large that this task is too time consuming to be performed routinely. This is gradually changing, however. An increasing number of proteins structures, primarily those solved at atomic resolution, have their s.u.'s computed in this manner (Deacon *et al.*, 1997; Harata *et al.*, 1998). A program often used for this purpose is *SHELXL* (Sheldrick & Schneider, 1997), a well known refinement software package for small molecules that has recently been extended to proteins. Availability of s.u.'s can determine the dependence of the precision of the atomic coordinates on various factors, such as the resolution, the atomic number, and the number and types of restraints used during refinement (Tickle *et al.*, 1998).

Other methods for determining the relative precision of atoms in macromolecular structures involve calculating the agreement between the model and the electron density in specific regions.

Table 21.2.3.1
Parameters computed for the analysis of the structure-factor data

The first column lists the parameter, the second column gives the formula or definition of the parameter and the third column contains a short description of the meaning of the parameters when warranted.

Parameter	Formula/definition	Meaning
Completeness (%)	Percentage of the expected number of reflections for the given crystal space group and resolution	
B_overall (Patterson)	$8\pi^2\sigma_{\rm Patt}/(2)^{1/2}$†	Overall B factor
R_stand(F)	$\langle\sigma(F)\rangle/\langle F\rangle$‡	Uncertainty of the structure-factor amplitudes
Optical resolution	$(\sigma^2_{\rm Patt}+\sigma^2_{\rm sph})^{1/2}$† §	Expected minimum distance between two resolved atomic peaks
Expected optical resolution	Optical resolution computed considering all reflections	
CC_F	$\dfrac{\langle F_{\rm obs}F_{\rm calc}\rangle-\langle F_{\rm obs}\rangle\langle F_{\rm calc}\rangle}{\left[(\langle F^2_{\rm obs}\rangle-\langle F_{\rm obs}\rangle^2)(\langle F^2_{\rm calc}\rangle-\langle F_{\rm calc}\rangle^2)\right]^{1/2}}$	Correlation coefficient between the observed and calculated structure-factor amplitudes
S	$\left\{\dfrac{\sum(F_{\rm obs}f_{\rm cutoff})^2}{\sum\left[F_{\rm calc}\exp(-B^{\rm overall}_{\rm diff}s^2)f_{\rm cutoff}\right]^2}\right\}^{1/2}$ ¶	Factor applied to scale $F_{\rm calc}$ to $F_{\rm obs}$
$f_{\rm cutoff}$	$1-\exp(-B_{\rm off}s^2)$††	Function applied to obtain a smooth cutoff for low-resolution data

† $\sigma_{\rm Patt}$ is the standard deviation of the Gaussian fitted to the Patterson origin peak. ‡ F is the structure-factor amplitude, and $\sigma(F)$ is the structure-factor standard deviation. The brackets denote averages. § $\sigma_{\rm sph}$ is the standard deviation of the spherical interference function, which is the Fourier transform of a sphere of radius $1/d_{\rm min}$, with $d_{\rm min}$ being the minimum d spacing. ¶ $B^{\rm overall}_{\rm diff}=B^{\rm overall}_{\rm obs}-B^{\rm overall}_{\rm calc}$ is added to the calculated overall B factor, $B_{\rm overall}$, so as to make the width of the calculated Patterson origin peak equal to the observed one; s is the magnitude of reciprocal-lattice vector. †† $B_{\rm off}=4d^2_{\rm max}$, where s and $d_{\rm max}$, respectively, are the magnitude of the reciprocal-lattice vector and the maximum d spacing.

The newer approach by Zhou *et al.* (1998) is related to the real-space R factor of Jones *et al.* (1991), but differs from it by the way in which the electron density is computed (Chapman, 1995).

As our understanding of the factors that govern the systematic errors in macromolecular crystallography increases and our ability to detect random errors improves, the possibility of devising systematic and possibly more automatic protocols for assessing the agreement between the model and the data will emerge.

In what follows, we describe the software package *SFCHECK* (Vaguine *et al.*, 1999), which can be regarded as a first attempt in this direction. This software computes and summarizes many of the commonly used measures for evaluating the quality of the structure-factor data and the agreement of the model with these data.

We summarize the tasks performed and the quality indicators computed by *SFCHECK* and briefly illustrate how this software can be used to evaluate individual structures and survey different structures.

21.2.3.1. A systematic approach using the SFCHECK software

21.2.3.1.1. Tasks performed by SFCHECK

21.2.3.1.1.1. Treatment of structure-factor data and scaling

SFCHECK reads in the structure-factor data written in mmCIF format. It then performs the following operations: Reflections are excluded if they are systematically absent, negative, or have flagged σ values (99.9). Equivalent reflections are merged. The amplitudes of missing reflections are approximated by taking the average value for the corresponding resolution shell.

From the model coordinates read from the PDB (or mmCIF) atomic coordinates file, *SFCHECK* calculates structure factors and scales them to the observed structure factors. The scaling factor, S, is computed using a smooth cutoff for low-resolution data (Vaguine *et al.*, 1999) (Table 21.2.3.1). This involves the calculation of the observed and calculated overall B factors from the standard deviations of the Gaussian fitted to the Patterson origin peaks [see Table 21.2.3.1 and Vaguine *et al.* (1999)]. In addition, *SFCHECK* also estimates the overall anisotropy of the data, following the approach of Sheriff & Hendrickson (1987), and applies the anisotropic scaling after the Patterson scaling is performed (Murshudov *et al.*, 1998).

To assess the quality of the structure-factor data, the program computes four additional quantities (see Table 21.2.3.1 for details): the completeness of the data, the uncertainty of the structure-factor amplitudes, the optical resolution and the expected optical resolution. The latter two quantities represent the expected minimum distance between two resolved atomic peaks in the electron-density map when the latter is computed with the set of reflections specified by the authors and with all the reflections, respectively.

21.2.3.1.1.2. Global agreement between the model and experimental data

To evaluate the global agreement between the atomic model and the experimental data, the program computes three classical quality indicators: the R factor, $R_{\rm free}$ (Brünger, 1992*b*) and the correlation coefficient CC_F between the calculated and observed structure-factor amplitudes (Table 21.2.3.1). The R factor is computed using all the reflections considered (except those approximated by their average value in the corresponding resolution shell) and applying the same resolution and σ cutoff as those reported by the authors. $R_{\rm free}$ is computed using the subset of reflections specified by the authors. In addition, the R factor is evaluated using the 'non-free' subset of reflections (those not used to compute $R_{\rm free}$). The correlation coefficient is computed using all reflections from the reported high-resolution limit, applying the smooth low-resolution cutoff (see Table 21.2.3.1) but no σ cutoff.

Table 21.2.3.2
Estimation of errors in atomic coordinates

The first column lists the parameter, the second column gives the formula or definition of the parameter and the third column contains a short description of the meaning of the parameters when warranted.

Parameter	Formula/definition	Meaning
$\sigma(x)$	$\dfrac{\sigma(\text{slope})}{\text{curvature}}$†	Standard deviation of the atomic coordinates following Cruickshank (1949) for the minimal and maximal errors (Vaguine *et al.*, 1999)
σ(slope) for maximal error	$\dfrac{2\pi\{\sum[h^2(F_{\text{obs}}-F_{\text{calc}})^2]\}^{1/2}}{V_{\text{unit cell}}a}$‡	Expression for σ(slope) in the expected maximal error following Cruickshank (1949)
Curvature	$\dfrac{2\pi\sum(h^2F_{\text{obs}})}{V_{\text{unit cell}}a^2}$	Expression for the curvature following Murshudov *et al.* (1997)
σ(slope) for minimal error	$\dfrac{2\pi^2\{\sum[h^2\sigma(F_{\text{obs}})^2]\}^{1/2}}{V_{\text{unit cell}}a}$§	Expression for σ(slope) in the expected minimal error, following Cruickshank (1949)
DPI	$\sigma(x)=\left(\dfrac{N_{\text{atoms}}}{N_{\text{obs}}-4N_{\text{atoms}}}\right)^{1/2}c^{-1/3}d_{\min}R$¶	Atomic coordinate error estimate following Cruickshank (1996)

† σ(slope) and curvature are the slope and curvature of the electron-density map at the atomic centre, in the x direction, for spherically symmetric peaks; $\sigma(x)\simeq\sigma(y)\simeq\sigma(z)$. ‡ a is the crystal unit-cell length, h is the Miller index and $V_{\text{unit cell}}$ the unit-cell volume. § $\sigma(F_{\text{obs}})$ is the standard deviation of the structure-factor amplitude. ¶ c is the structure-factor data completeness expressed as a fraction (0–1), R is the conventional R factor, N_{atoms} is the total number of atoms in the unit cell, N_{obs} is the total number of observed reflections and $d_{\min}$ is the minimum d spacing.

21.2.3.1.1.3. Estimations of errors in atomic positions

The errors associated with the atomic positions are expressed as standard deviations (σ) of these positions. *SFCHECK* computes three different error measures. One is the original error measure of Cruickshank (1949). The second is a modified version of this error measure, in which the difference between the observed and calculated structure factors is replaced by the error in the experimental structure factors. The first two error measures are the expected maximal and minimal errors, respectively, and the third measure is the diffraction-component precision indicator (DPI). The mathematical expressions for these error measures are given in Table 21.2.3.2, and further details can be found in Vaguine *et al.* (1999).

21.2.3.1.1.4. Local agreement between the model and the experimental data

In addition to the global structure quality measures, *SFCHECK* also determines the quality of the model in specific regions. Several quality estimators can be calculated for each residue in the macromolecule and, whenever appropriate, for solvent molecules and groups of atoms in ligand molecules. These estimators are the normalized atomic displacement (Shift), the correlation coefficient between the calculated and observed electron densities (Density correlation), the local electron-density level (Density index), the average B factor (B-factor) and the connectivity index (Connect), which measures the local electron-density level along the molecular backbone. These quantities are computed for individual atoms and averaged over those composing each residue or group of atoms [see Table 21.2.3.3 and Vaguine *et al.* (1999) for details].

21.2.3.1.2. Evaluation of individual structures

Figs. 21.2.3.1–21.2.3.3 summarize the analysis carried out by *SFCHECK* on the protein rusticyanin from *Thiobacillus ferrooxidans* (1RCY) (Walter *et al.*, 1996). Fig. 21.2.3.1 displays the numerical results from the analysis of the structure-factor data and from the evaluation of the global agreement between the model and the data. The R-factor and R_{free} values, computed by *SFCHECK* (Model vs. Structure Factors panel) using the identical reflection subset to that reported by the authors (Refinement panel), show negligible differences with the reported values. These differences are 0.175 *versus* 0.172 for the R factor and 0.25 *versus* 0.243 for R_{free}. The small R-factor difference may stem from the fact that *SFCHECK* considers a somewhat different number of reflections (9144) than the authors (9098), although it uses the same d-spacing range and σ cutoff as those reported.

The information in Figs. 21.2.3.1 and 21.2.3.2 allows one to make some judgement about the quality of the structure-factor data for this protein. The relatively high resolution of this structure (1.9 Å) is accompanied by limited data completeness (82.1%). The Rstand(F) plot on the same graph shows, furthermore, a decrease in quality of the high-resolution data (2.2–1.9 Å). The average radial completeness plot (bottom left-hand plot of Fig. 21.2.3.2) allows one to identify the regions in reciprocal space with incomplete data.

Fig. 21.2.3.3 presents the *SFCHECK* analysis of the local agreement of the model with the electron density for 1RCY. The shift plot shows that both backbone and side-chain shifts are of comparable size, with several residues (1, 2, 16, 25) displaying shifts as high as 0.16 Å. The density correlation is excellent throughout the entire molecule, except for residues 2, 16 and 29, which display poorer correlation. In particular, the side chains of these residues seem to be more poorly defined in the electron-density map. The backbone density index plunges in a few regions, notably at the N-terminus (residues 5–7) and in the segments comprising residues 25–30 and 68–70. The side chains display, in general, a poorer density index than the backbone, with some regions (for example, residues 5–7, 23–30, 58–60) displaying rather low density indices. The same segments also display higher backbone and side-chain B factors. The backbone Connect parameter is, on the other hand, quite good throughout, except for residues 5–7 and 28–29 (Fig. 21.2.3.3).

Water molecules (labeled w in the *SFCHECK* output) are also evaluated. The relevant plots for these molecules are those of the Shift, Density index and B factor parameters. The first 50 or so water molecules in the list (appearing sequentially along the plot from left to right) tend to display a higher density index and lower B factors (< 30 Å^2) than the following molecules in the list.

Figure 21.2.3.1

Typical *SFCHECK* output in PostScript format, illustrated for the protein rusticyanin from *Thiobacillus ferrooxidans* (1RCY) (Walter *et al.*, 1996). Summary panels displaying the numerical results from the analysis of the deposited structure-factor data and from the evaluation of the global agreement between the model and these data. The top elongated panel lists the PDB title record, deposition date and PDB code. The Crystal panel summarizes the crystal parameters, provided by the authors, as read from the model input files. The Model and Refinement panels list the information provided by the authors on the model and the refinement procedure, respectively. This information is read from the PDB coordinates entry. The Structure Factors panel summarizes the information on the deposited structure-factor data (Input section) and on the data used and criteria computed by *SFCHECK* (SFCHECK section). The numbers given under 'Anisotropic distribution of Structure Factors' are the ratios of the eigenvalues of the symmetric anisotropic thermal tensor to the maximum eigenvalues. The Model vs. Structure Factors panel summarizes the results of the verifications made by *SFCHECK*. The values listed under 'Anisothermal Scaling (Beta)' are those of the overall anisotropic thermal tensor ($b_{11}, b_{12}, b_{13}, b_{22}, b_{23}, b_{33}$). The meanings of other listed quantities are either self-explanatory or are described in the text.

They thus seem to be more reliably positioned than subsequent molecules, whose density indices sometimes drop perilously. A steady climb of the B factors is also apparent as one goes down the list of water molecules. The analysis of the density indices and B factors of individual water molecules performed by *SFCHECK* could be a very useful guide in investigations of the properties of crystallographic water molecules and their interactions with protein atoms.

21.2.3.1.3. Quality assessment based on surveys across structures

21.2.3.1.3.1. Assessing the quality of a structure as a whole

As for the evaluation of the geometric and stereochemical parameters of the model, surveying the same quality indicators across many structures is crucial. It allows one to establish the ranges of expected values for each indicator and to identify structures with unexpected features – those for which the values of one or more quality indicators are outside their standard range.

The global quality indicators computed by *SFCHECK* are the nominal resolution (d spacing), the R factor, $R_{\rm free}$, the minimal and maximal errors in atomic positions, the DPI, and the correlation coefficient CC_F. Another type of global quality indicator can be obtained by computing the average values of local quality measures across a given structure. This can be done for the per-residue (or per-group) atomic displacement and the Density correlation and B factor parameters as well as for the Density index and Connect parameters.

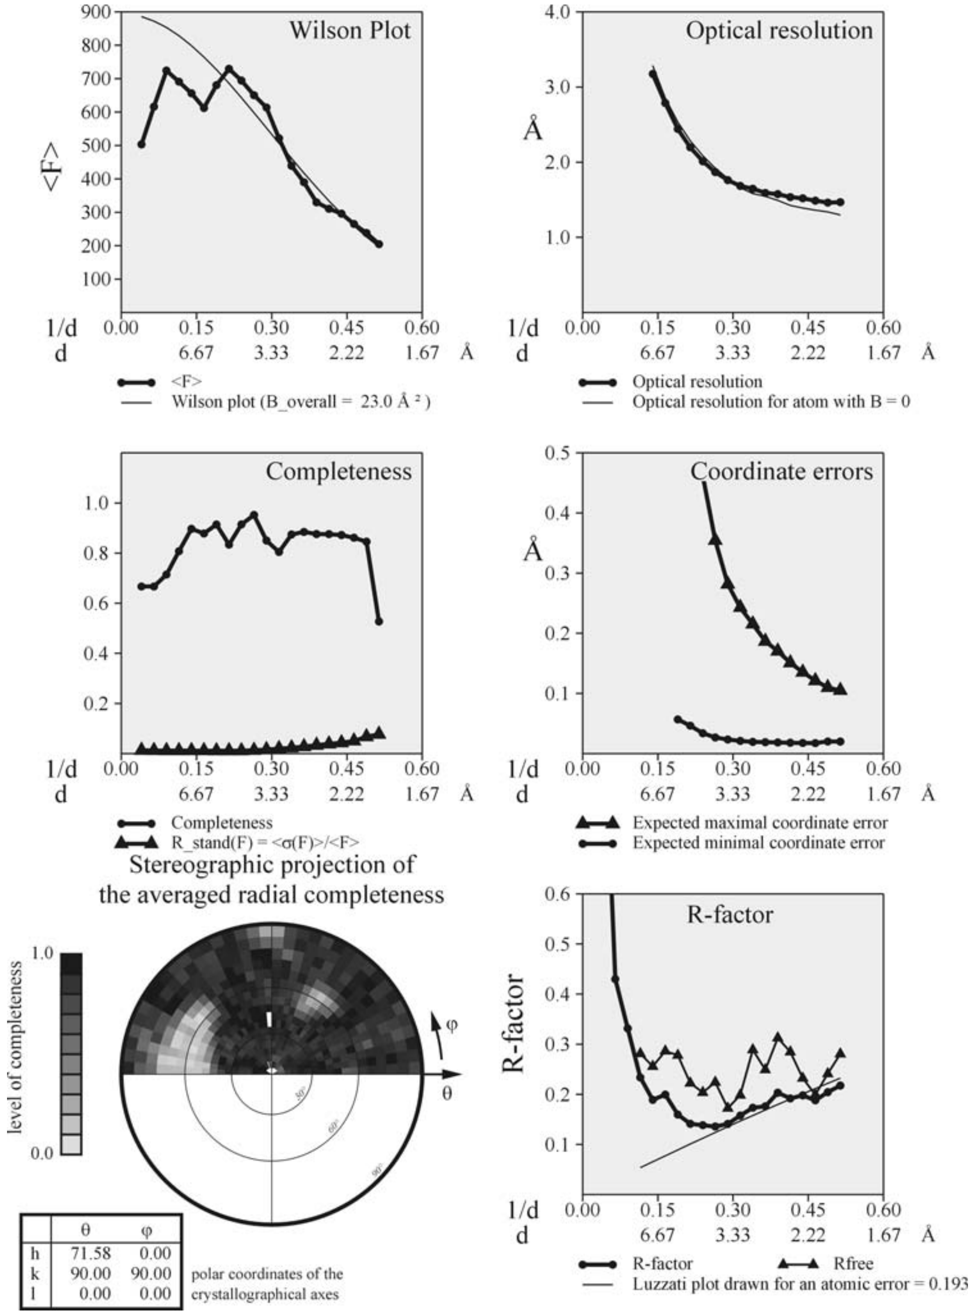

Figure 21.2.3.2

Graphical output from the *SFCHECK* analysis of global characteristics of the structure-factor data and the model agreement with those data for the same structure as in Fig. 21.2.3.1. From left to right and top to bottom: the Wilson plot; the behaviour of the optical resolution as a function of the nominal resolution (*d* spacing); the data completeness and structure-factor standard error as a function of the *d* spacing; the maximal and minimal coordinate error dependence on *d* spacing; a stereographic projection of the averaged radial structure-factor data completeness; and, finally, the *R*-factor dependence and Luzzati plots for a given atomic error.

Many of the geometric and stererochemical quality indicators vary as a function of resolution – some linearly and some not (Laskowski *et al.*, 1993). This is also the case for most of the global quality indicators described here. Examples of this dependence are given in Fig. 21.2.3.4, which shows how the correlation coefficient, the maximal error, the average atomic displacement and average density index vary as a function of resolution in the 104 nucleic acid structures surveyed. This variation is approximately linear for all four parameters. The density correlation and average density index decrease, whereas the maximal error and average atomic displacements increase, as the resolution gets poorer. In all four plots of Fig. 21.2.3.4, the points tend to display significant scatter as the *d* spacing increases, and at least three points, corresponding to the same three structures, appear as outliers in all plots. These structures also appear as outliers in the analysis of other parameters. A closer examination revealed that in the vast majority of the cases, the abnormal behaviour of these structures could be traced back to problems with data formats or errors that occurred during data deposition and entry processing.

As the number of structures with deposited structure-factor data becomes large enough, plots such as those of Fig. 21.2.3.4 could be used to define the expected range of values for a quality indicator in a structure determined at a given resolution or refined under given conditions. Structures yielding quality indicators outside this range could then be identified as unusual on a more solid statistical basis.

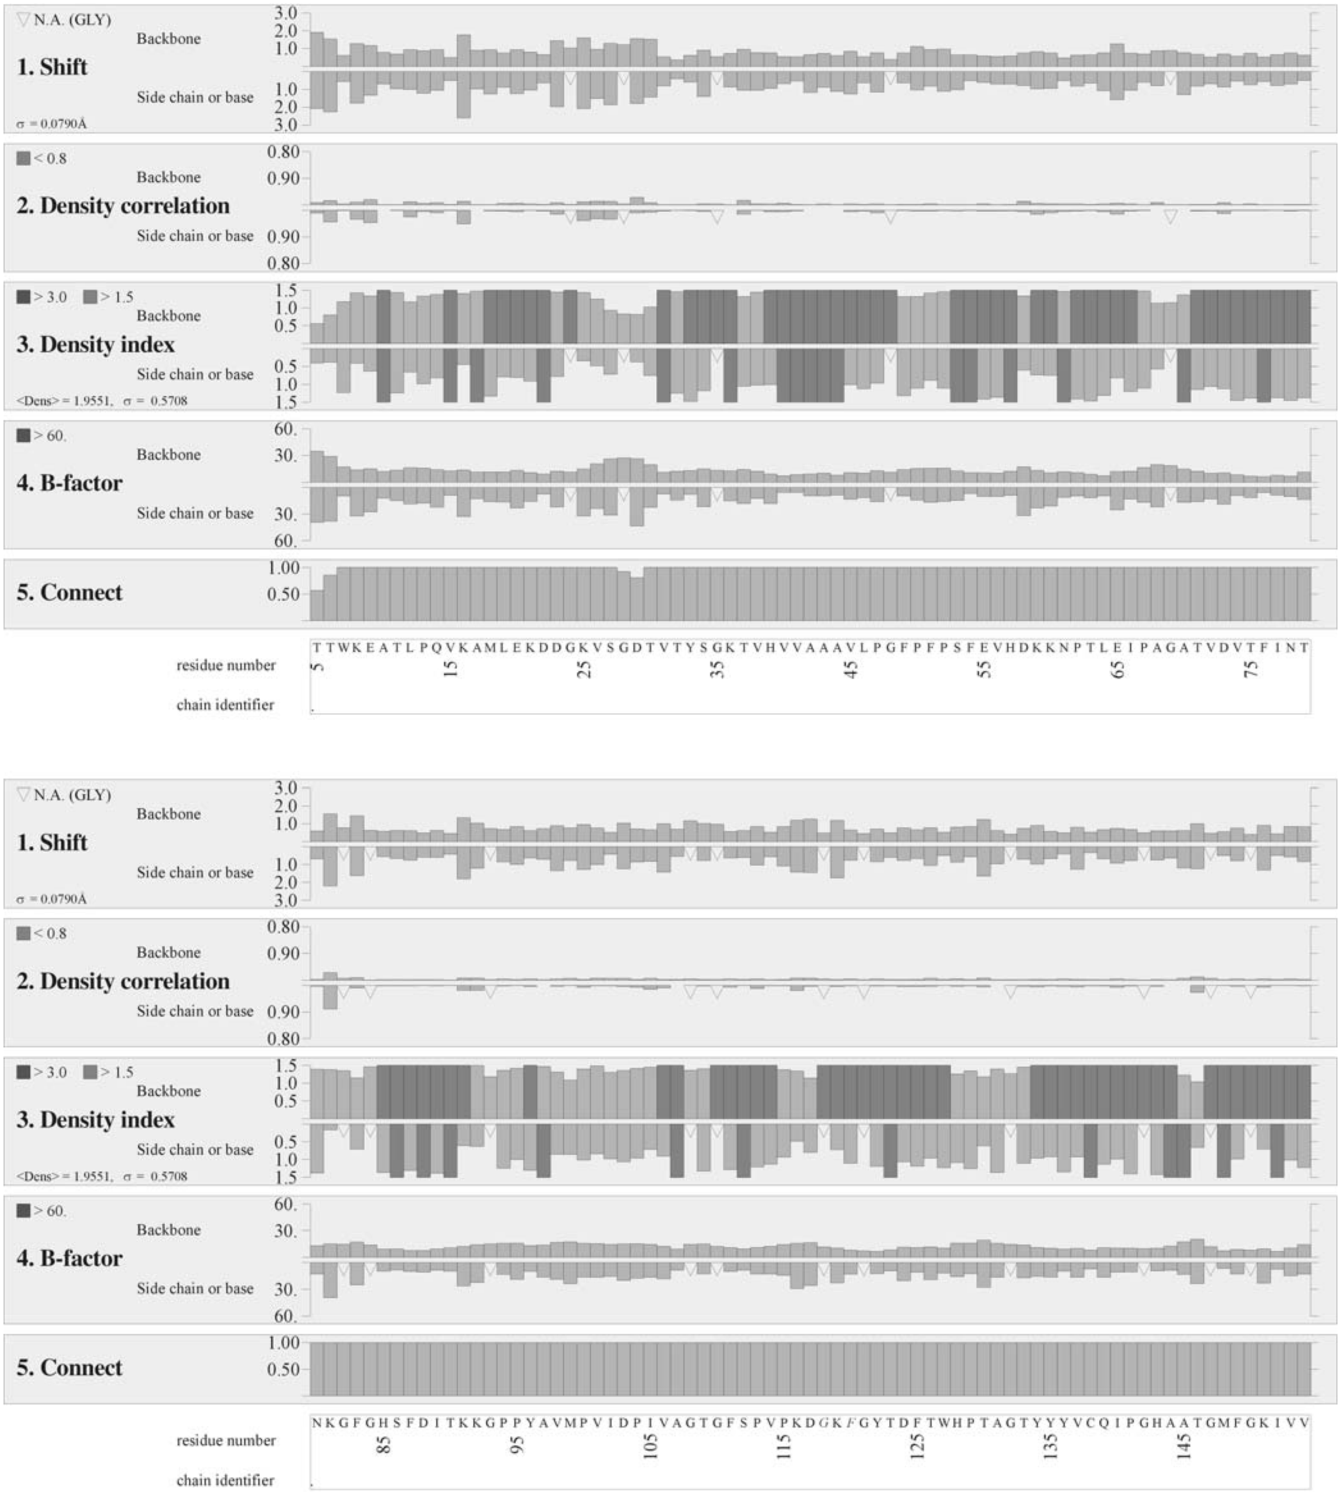

Figure 21.2.3.3

SFCHECK evaluation summary of the local agreement between the model and the electron density for the same structure as in Fig. 21.2.3.1. Five criteria are plotted for each residue of the macromolecule (designated by its one-letter code), as well as for each solvent molecule (w), or hetero group. These criteria are: (1) Shift, (2) Density correlation, (3) Density index, (4) B factor, (5) Connect. The definitions of these criteria are given in the text. Note that the values of the Connect parameter are truncated to a maximum of 1. The *SFCHECK* output shown in Figs. 21.2.3.1–21.2.3.3 was generated using routines from *PROCHECK* kindly provided by R. Laskowski.

21.2.3.1.3.2. Assessing the quality in specific regions of a model

The main purpose for computing the four local quality measures, the B factor, the Density index, the atomic displacement (Shift) and the Density correlation (Table 21.2.3.3), is to identify problem regions in a model. In order to do this effectively, it is necessary to evaluate the degree of redundancy between these measures and to establish the standard ranges for their values. The latter task, in particular, is not straightforward since it depends crucially on the quality of the experimental data and biases introduced by the scaling procedure and refinement protocol. In this regard, several issues are presently still under investigation.

A preliminary investigation of the mutual relations between the above-mentioned local measures has been performed in several protein and nucleic acid structures taken individually.

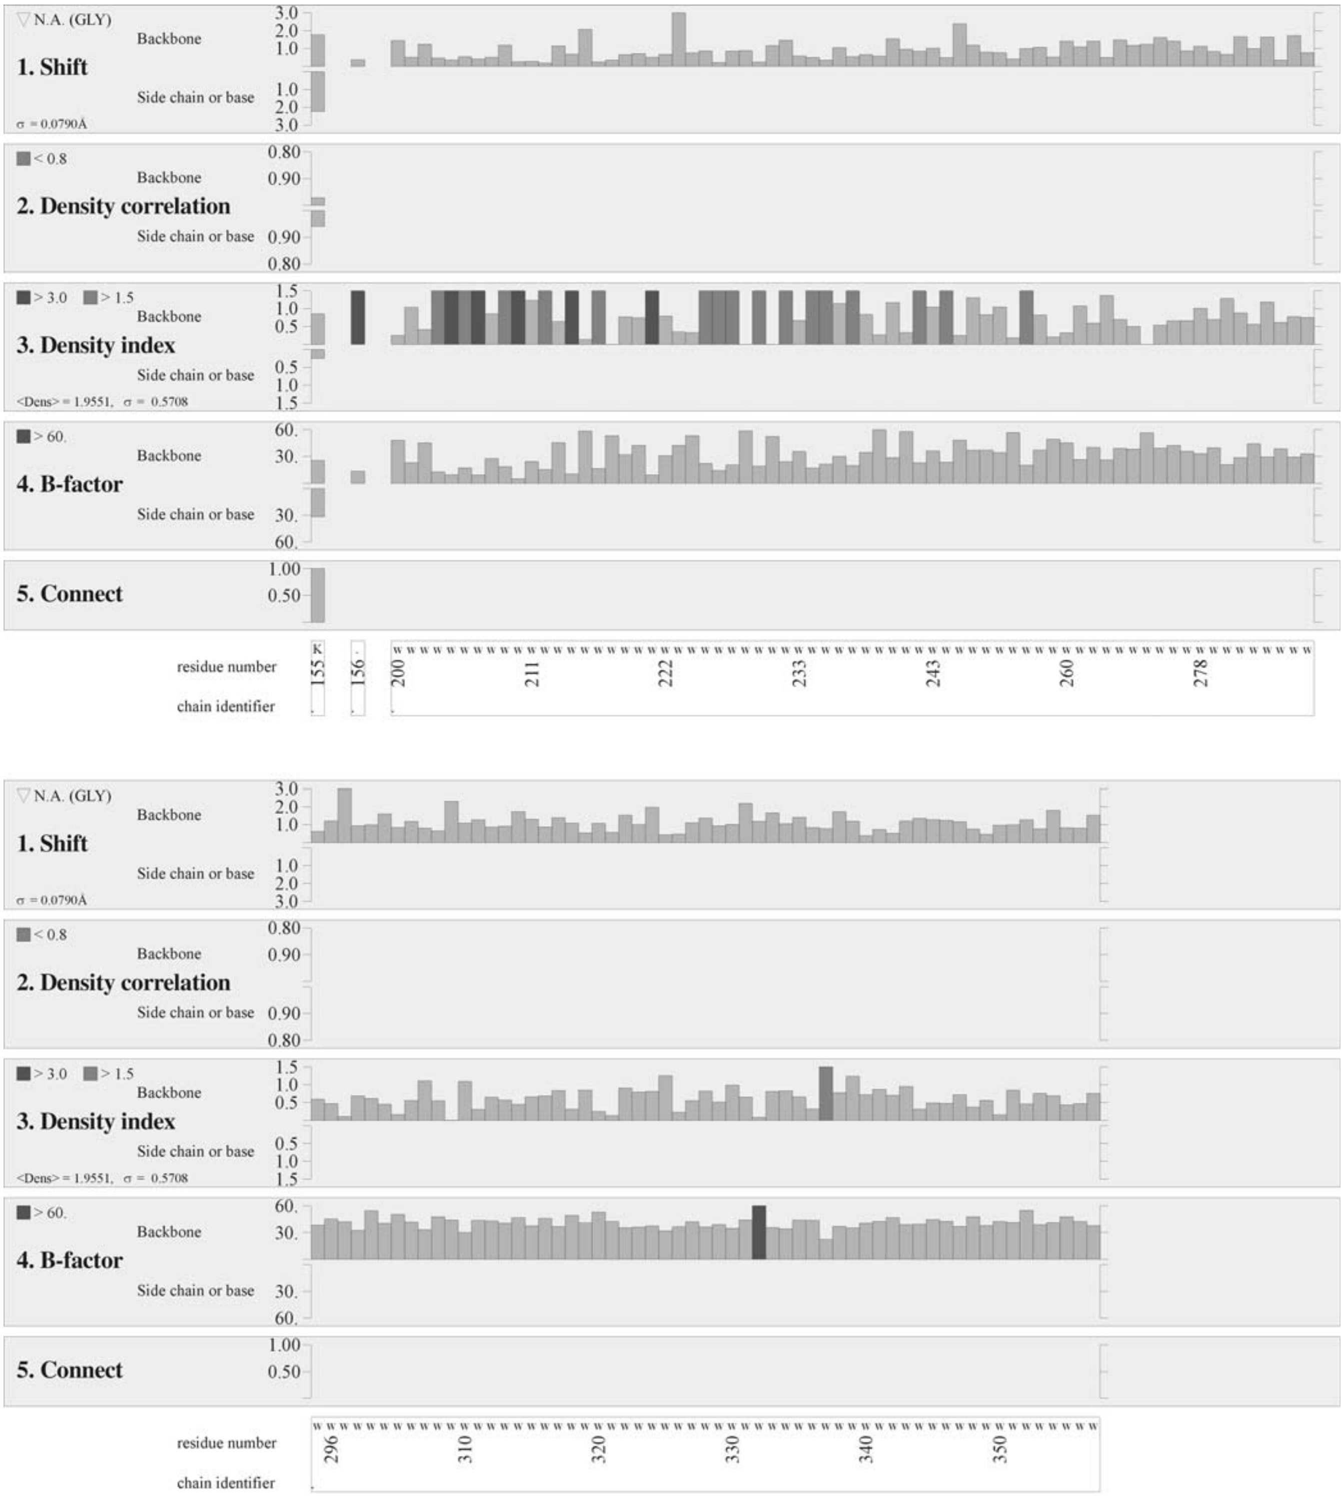

Figure 21.2.3.3 (continued)

This shows that the B factor is strongly correlated with the density index, as illustrated in Fig. 21.2.3.5(a), and to a lesser extent with the atomic displacement (Fig. 21.2.3.5b). A weaker correlation was detected between the latter three measures and the residue density correlation (data not shown).

Analyses across structures could, in principle, be carried out for all four local measures computed by *SFCHECK*, provided these measures are not subject to systematic biases due to differences in scaling procedures and refinement practices. Such biases are, however, well known for the B factors of individual atoms or residues. This is illustrated in Fig. 21.2.3.6(a). This figure plots, side-by-side, the average residue B factors in 21 protein structures determined at different d spacings. It shows that for proteins determined at poorer resolution (d spacing above 2 Å), the B factors of different structures are systematically shifted relative to one another. Such systematic shifts are much smaller for structures determined at 2 Å resolution or better (Fig. 21.2.3.6a). This is not surprising, since in lower-resolution structures, $N_{\text{refl}}/N_{\text{atoms}}$ is often too low (< 4) to yield meaningful values for the B factors.

Interestingly, the residue Density index, a very different parameter from the B factor, which measures the level of electron density at the atomic positions, does not display the systematic shifts observed for the B factors (Fig. 21.2.3.6b), despite the fact

Table 21.2.3.3
Parameters computed by *SFCHECK* to assess the quality of the model in specific regions

The first column lists the parameter, the second column gives the formula or definition of the parameter and the third column contains a short description of the meaning of the parameters when warranted.

Parameter	Formula/definition	Meaning
Shift	$(1/N\sigma)\sum_{i}^{N}\Delta_i$, with $\Delta_i = (\text{gradient}_i/\text{curvature}_i)$†	Normalized average atomic displacement computed over a group of atoms or residue; reflects the tendency of the group of atoms to move from their current position
Density correlation	$\dfrac{\sum\rho_{\rm calc}(x_i)[2\rho_{\rm obs}(x_i)-\rho_{\rm calc}(x_i)]}{\left(\left[\sum\rho^2_{\rm calc}(x_i)\right]\left\{\sum[2\rho_{\rm obs}(x_i)-\rho_{\rm calc}(x_i)]^2\right\}\right)^{1/2}}$‡	Electron density correlation coefficient computed over a group of atoms or residue; reflects the local agreement of the model with the electron density
Density index	$\left[\prod\rho(x_i)\right]^{1/N}/\langle\rho\rangle_{\text{all atoms}}$§	Reflects the level of the electron density for a group of atoms; is a local measure of the density level
Connect		Same as Density index, but considering only backbone atoms¶

† Gradient$_i$ is the gradient of the $F_{\rm obs}-F_{\rm calc}$ map with respect to the atomic coordinates, curvature$_i$ is the curvature of the model map computed at the atomic centre (see Agarwal, 1978), N is the number of atoms in the group considered and σ is the standard deviation of the Δ_i values computed in the structure. ‡ $\rho_{\rm calc}(x_i)$ and $\rho_{\rm obs}(x_i)$ are, respectively, the electron density computed from calculated and observed structure-factor amplitudes at the atomic centre. The summation is performed over all the atoms in the group considered. For polymer residues, D_corr is computed separately for backbone and side-chain atoms. For the calculation of the electron density at the atomic centre, see Vaguine *et al.* (1999). § $[\prod\rho(x_i)]^{1/N}$ is the geometric mean of the $2F_{\rm obs}-F_{\rm calc}$ electron density of the atom subset considered and $\langle\rho\rangle_{\text{all atoms}}$ is the average electron density of the atoms in the structure. For water molecules or ions which are represented by a unique atom, the above expression reduces to the ratio $\rho(x_i)/\langle\rho\rangle_{\text{all atoms}}$. ¶ Backbone atoms are N, C, C$^{\alpha}$ for proteins and P, O5′, C5′, C3′, O3′ for nucleic acids.

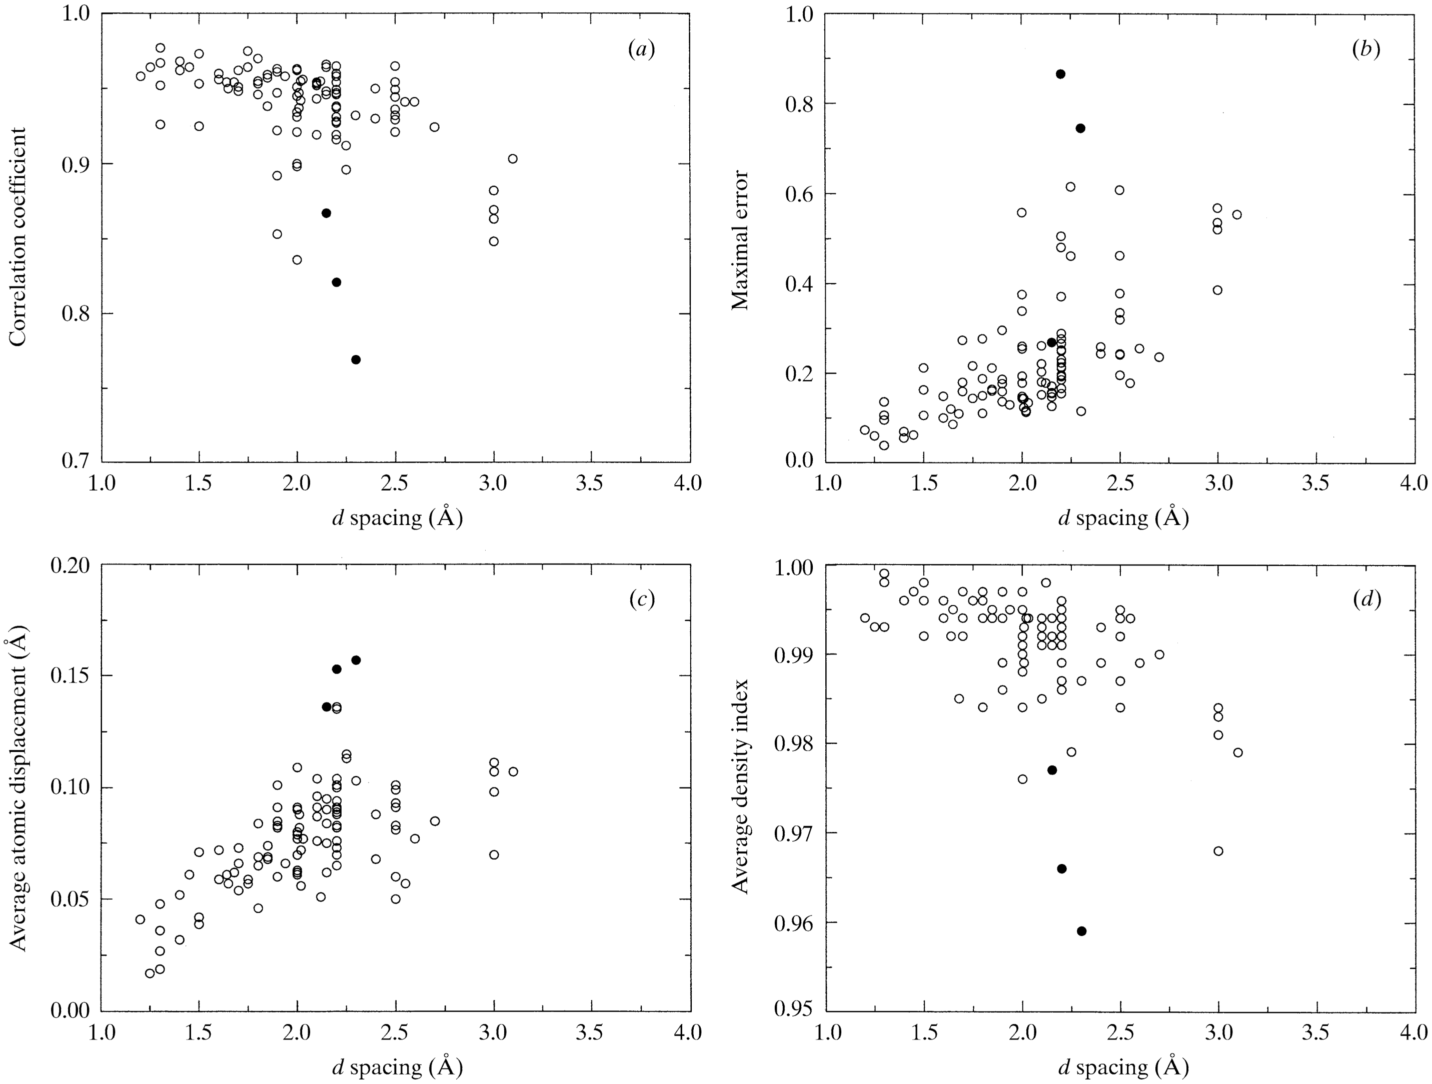

Figure 21.2.3.4
Variation of global quality indicators with the nominal resolution (d spacing) of the crystallographic data. The following quality indicators were computed by *SFCHECK* for each of the 104 nucleic acid crystal structures considered in the study of Das *et al.* (2001): (*a*) correlation coefficient, (*b*) maximal error, (*c*) average atomic displacement and (*d*) average density index. For the meaning of the various quantities see Table 21.2.3.2. The three structures for which the reported and re-computed R factors differ by more than 10% are highlighted as black circles. The NDB (PDB) codes for these structures are ADFB72 (256D), ADF073 (257D) and ADJ081 (320D).

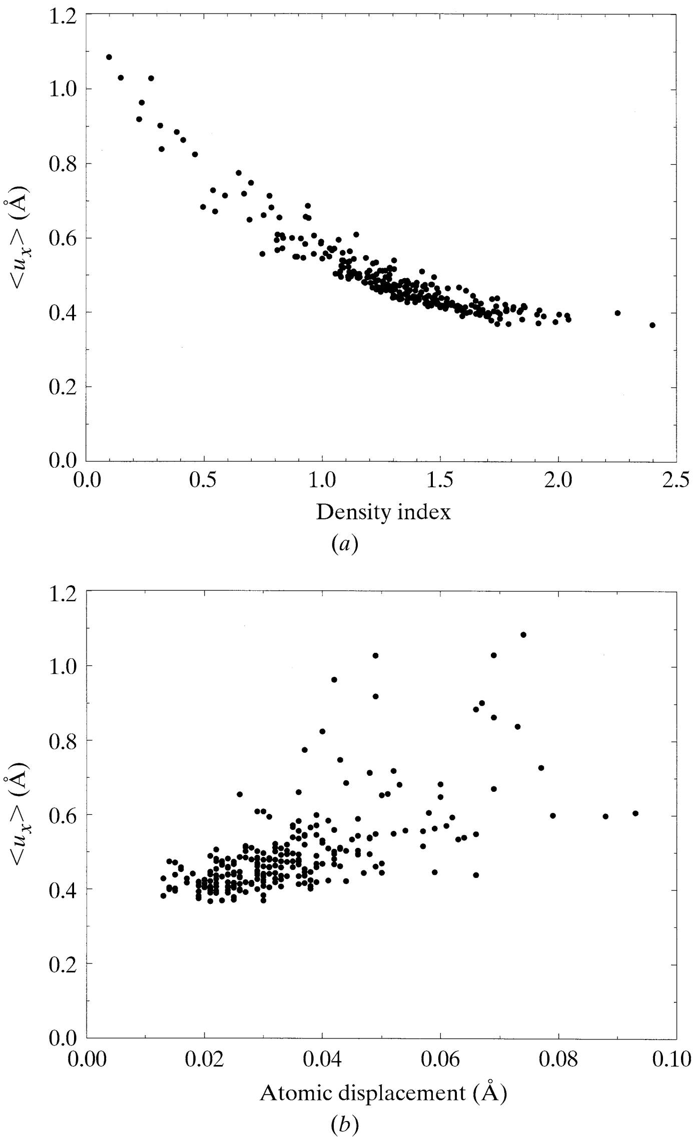

Figure 21.2.3.5

Pairwise correlations between the various local quality indicators computed by *SFCHECK*. (*a*) Correlation between the average residue *B* factor and the density index, and (*b*) between the *B* factor and the atomic displacement. The values displayed were computed for residues in the crystal structure of carboxypeptidase (1YME). The meaning of the parameters displayed is given in Table 21.2.3.3.

that the two measures are rather strongly correlated in individual structures. An indicator such as this one, and ultimately the atomic s.u.'s themselves, should be better suited for analysing and comparing the trends in the quality of specific regions of the model across different structures.

21.2.4. Atomic resolution structures

With improved techniques of crystallization and data collection using synchrotron radiation and cryogenic cooling, an increasing number of protein crystal structures are being determined at atomic resolution (1.2 Å or better). With atomic resolution data, refinement can be performed that requires much less strict compliance with prior knowledge of the expected geometry. Although some restraints must still be imposed, especially to deal with more flexible regions, and hence biases remain, it might be expected that these structures provide more precise information on the 'true' geometrical and stereochemical properties of proteins. Ultimately, one would want to re-derive these properties using only atomic resolution structures, but their number is at present too limited to provide sufficient data for a meaningful statistical analysis.

In the meantime, atomic resolution protein structures have been used to check geometric and conformational parameters that have been derived from other sources, including small-molecule crystals and the larger set of proteins determined at various levels of resolution (Longhi *et al.*, 1997; EU 3-D Validation Network, 1998). The EU 3-D Validation Network study showed that in the atomic resolution structures, most of the geometrical validation parameters are more tightly clustered about their mean value than in structures determined at lower resolution, including tighter clustering in the core regions of the Ramachandran plot, tighter clustering of the atomic volumes and smaller s.u.'s in the distributions of the χ_1, χ_2 dihedral angles. In contrast, the ω torsion angle about the peptide bond exhibits a wider distribution, with a mean of 179.0 (56)° compared to 179.6 (47)° previously computed in protein structures determined at various resolution levels (Morris *et al.*, 1992).

Recently, atomic resolution structures have also been used to derive atomic s.u values for proteins. Remarkably, the estimated coordinate errors for concanavalin A at 0.94 Å (Deacon *et al.*, 1997) were found to be equivalent to those of small-molecule crystal structures, despite the large size of the protein (237 residues).

Atomic resolution structures of proteins and other macromolecules thus promise to represent a valuable source of accurate information on geometric and conformational parameters of these molecules. But the analysis and validation of such structures also brings about additional complications, such as, for example, the problem of dealing with equilibria between multiple conformations, which atomic resolution data tend to resolve with much higher detail and accuracy. Handling these equilibria will require an adaptation of the current validation procedures.

21.2.5. Concluding remarks

The coming years will see an ever-increasing number of crystal structures of proteins and nucleic acids determined at high resolution and a substantial growth in the number of atomic resolution structures. This will most certainly help in obtaining better data on the geometric and stereochemical parameters of these macromolecules and thus improve the target values for both refinement and structure validation. It should also make it possible to derive better criteria for evaluating the agreement of the model with the electron density and to improve upon and generalize comprehensive and systematic approaches, such as that implemented in the software *SFCHECK*.

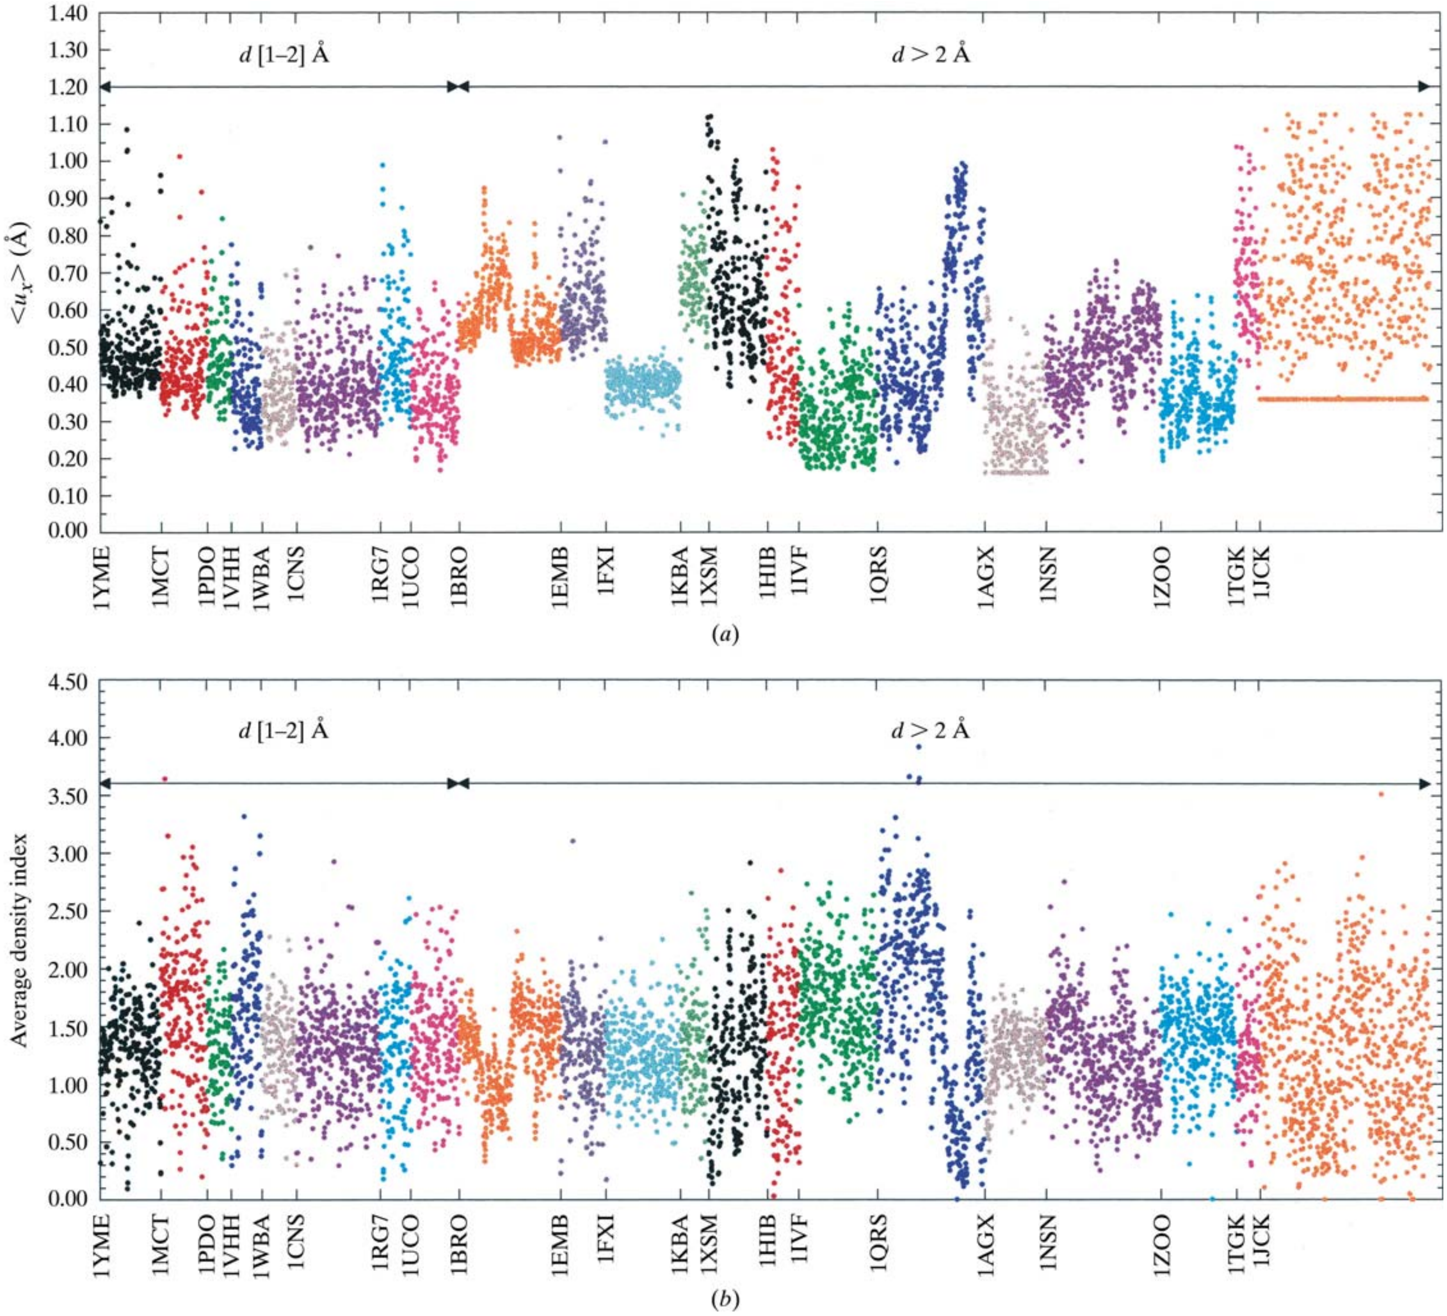

Figure 21.2.3.6

B factors and density indices for residues across different structures. (*a*) Average *B* values in residues of 21 protein structures; (*b*) average density indices of the same set of residues and structures. The 21 protein structures analysed are from the following PDB entries: 1YME, 1MCT, 1PDO, 1VHH, 1WBA, 1CNS, 1RG7, 1UCO, 1BRO, 1EMB, 1FXI, 1KBA, 1XSM, 1HIB, 1IVF, 1QRS, 1AGX, 1NSN, 1ZOO, 1TGK, 1JCK.

Chapter 21.3. Detection of errors in protein models

O. Dym, D. Eisenberg and T. O. Yeates

21.3.1. Motivation and introduction

The discovery of major errors in several protein structural models determined by X-ray crystallography has focused attention on methods of detecting and minimizing such errors. There are several sources of error in the determination of a protein structure. Errors enter not only in the collection of the experimental data, but especially in their interpretation. Limited diffraction resolution and poor phases frequently lead to electron-density maps that are difficult to interpret. As a result, preliminary protein models built into ambiguous maps often contain errors of various types. The different types of errors can be arranged in decreasing order of severity, as follows: mistracing of the protein chain due to uncertainty in backbone connectivity, misalignment or misregistration of residues, and misplacement of side-chain and backbone atoms. It is critical to be able to identify these problematic regions of a model so they can be given special attention during the iterative process of model building and atomic refinement.

During atomic refinement, the atomic coordinates of the macromolecule are adjusted to minimize an error function of two terms. The first term contains the discrepancies between the observed diffraction data and structure factors calculated from the model. The second term describes the deviations from ideal geometry, such as deviations in bond lengths, bond angles, planarity and other specific features. When refinement is complete, the residual errors in the separate terms are reported, with the discrepancies in the diffraction data embodied in the R value. These error values are usually taken as the first indicators of structure quality.

Beyond criteria that are explicitly minimized during refinement, other structural properties may be devised and evaluated. Some properties that have been investigated include the distribution of non-polar and polar residues both on the surface and in the interior of the protein, and preferred environments for different atom types and residues. These measures use the empirical knowledge gathered in the Protein Data Bank (PDB) to assess how ‘normal’ or ‘abnormal’ a given model is. The measures are also useful in cases in which the experimental diffraction data are not available (*e.g.* when assessing structures already in the data bank). Several programs that validate protein structural models on the basis of various structural properties are available. Among them are *PROCHECK* (Laskowski *et al.*, 1993), *WHAT IF* (Vriend, 1990; Vriend & Sander, 1993), *ERRAT* (Colovos & Yeates, 1993), and *VERIFY3D* (Lüthy *et al.*, 1992; Bowie *et al.*, 1991). The various programs have the same objectives, but differ in many important respects. The approaches differ with regard to the scale of the analysis (*e.g.* atom-based *versus* amino-acid based), the level of detail in the program output, and the degree to which the evaluated properties are independent of the refinement function.

21.3.2. Separating evaluation from refinement

Any property that has been constrained or heavily restrained during refinement of the atomic model, and any property that has been closely monitored during rebuilding, cannot be used as the sole criterion to assess or ‘prove’ the quality of the model. The reason is that if the atomic model is adjusted to optimize a particular property, that property no longer gives an unbiased measure of model accuracy. For example, most refinement programs operate by adjusting atomic positions to minimize the difference between observed and calculated structure-factor amplitudes, known as the R factor or R value. Since the R value is the target of the optimization procedure, it does not provide an *independent* measure of quality. As a result, the ordinary R value can be misleading. A much more reliable measure is the free R value (Brünger, 1992), which is calculated from a randomly selected subset of the diffraction data that are excluded from the atomic refinement calculations. The importance of using the free R value to monitor refinement is now widely accepted.

Likewise, independent criteria must be employed to judge protein models themselves, aside from the diffraction data. Typical atomic refinement protocols tightly restrain the obvious stereochemical terms, such as bond lengths, angles and planarity. Therefore, low deviation from ideal geometry cannot be presented as proof of the quality of the structure. Independent criteria must be based on higher-level geometric considerations. Several programs that include such evaluations are described here.

Criteria that are useful for assessing the validity of protein models are those that are not directly restrained during the process of refinement. The following three properties of protein models are of this type: (1) the main-chain dihedral angles; (2) the non-bonded interactions of protein atoms with other protein atoms and with the solvent; and (3) the packing of atoms within the structure. Each of these properties of a proposed model can be compared for consistency with the same property observed in a database of trustworthy structures. To the extent that the property deviates from the values observed for the proteins of the database, the proposed model is suspect. Some of these properties can be computed for each segment of a protein or for local regions in three-dimensional (3D) space. In this way, inaccurate regions within a proposed model can be identified.

21.3.3. Algorithms for the detection of errors in protein models and the types of errors they detect

21.3.3.1. *PROCHECK*

The *PROCHECK* (Laskowski *et al.*, 1993) suite of programs compares the stereochemistry of a proposed protein model to stereochemical features of known structures. The program provides an assessment of the overall quality of the model by comparing the model with well refined structures of the same resolution, and also highlights regions that may need further adjustment. The output of *PROCHECK* comprises a number of plots, together with detailed residue-by-residue listings of secondary-structure assignment, non-bonded interactions between different pairs of residues, main-chain bond lengths and bond angles, and peptide-bond planarity.

Copyright © 2012 International Union of Crystallography

The program also displays main-chain dihedral angles (φ and ψ) as a two-dimensional Ramachandran (Ramachandran & Sasisekharan, 1968) plot. The Ramachandran plot classifies each residue in one of three categories: 'allowed' conformations; 'partially allowed' conformations, which give rise to modestly unfavourable repulsion between non-bonded atoms, and which might be overcome by attractive effects such as hydrogen bonds; and 'disallowed' interactions which give highly unfavourable non-bonded interatomic distances. The Ramachandran plot can identify unacceptable clusters of φ–ψ angles, revealing possible errors made during model building and refinement. As opposed to covalent bond angles and bond lengths, the main-chain dihedral angles are not usually restrained during X-ray refinement and therefore can be used to validate the structural model independently. In practice, the Ramachandran plot is one of the simplest, most sensitive tools for assessing the quality of a protein model.

The *PROCHECK* suite is generally useful for assessing the quality of protein structures in various stages of completion. The Ramachandran analysis is especially informative. However, it is possible, at least in principle, to devise an incorrect model with fully acceptable main-chain and side-chain stereochemistry, so other methods must also be used to assess protein models.

21.3.3.2. WHAT IF

The molecular modelling and drug design program *WHAT IF* (Vriend, 1990) performs a large number of geometrical checks, comparing a proposed protein model to a set of canonical distances and angles. These parameters include bond lengths and bond angles, side-chain planarity, torsion angles, interatomic distances, unusual backbone conformations and the Ramachandran plot. New additions (Vriend & Sander, 1993) include a 'quality factor', and a number of checks for clashes between symmetry-related molecules. Starting from the hypothesis that atom–atom interactions are the primary determinant of protein folding, the program tests a protein model for proper packing by calculating a contact quality index. Each contact is characterized by its fragment type (80 types from the 20 residues), the atom type and the three-dimensional location of the atom relative to the local frame of the fragment. Sets of database-derived distributions are compared with the actual distribution in the protein model being tested. A good agreement with the database distribution produces a high contact quality index. A low packing score can indicate any of: poor packing, misthreading of the sequence, bad crystal contacts, bad contacts with a co-factor, or proximity to a vacant active site. The contact analysis available in *WHAT IF* can be used as an independent quality indicator during crystallographic refinement, or during the process of protein modelling and design.

21.3.3.3. VERIFY3D

The program *VERIFY3D* (Lüthy *et al.*, 1992; Bowie *et al.*, 1991) measures the compatibility of a protein model with its own amino-acid sequence. Each residue position in the 3D model is characterized by its environment and is represented by a row of 20 numbers in a '3D profile'. These numbers are the statistical preferences, called 3D–1D scores, of each of the 20 amino acids for this environment. Environments of residues are defined by three parameters: the area of the residue buried in the protein and inaccessible to solvent, the fraction of the side-chain area that is covered by polar atoms (O and N), and the local secondary structure. The 3D profile score, S, for the compatibility of the sequence with the model is the sum, over all residue positions, of the 3D–1D scores for the amino-acid sequence of the protein. The compatibility of segments of the sequence with their 3D structures can be assessed by plotting, against sequence number, the average 3D–1D score in a window of 21 residues. The 3D profile method rests on the observation that soluble proteins bury many hydrophobic side chains and not many polar residues.

Three applications for 3D profiles exist. The first is to assess the validity of protein models (Lüthy *et al.*, 1992). For 3D protein models known to be correct, the 3D profile score, S, for the compatibility of the amino-acid sequence with the environments formed by the model is high. In contrast, S for the compatibility with its sequence of a totally or partially wrong 3D protein model is generally low. Therefore, models that are largely incorrect or models that contain a small number of improperly built segments can be detected by low-scoring regions in the 3D profile. However, not all faulty regions are always evident directly from the profile, particularly if the misbuilt regions are at the termini, where they are obscured by the windowing procedure. The second application is to assess which is the stable oligomeric state of the folded protein, by comparing the accessibility (buried or exposed) of amino-acid side chains in the monomeric and oligomeric state (Eisenberg *et al.*, 1992). The third application is to identify other protein sequences which are folded in the same general pattern as the structure from which the profile was prepared (Bowie *et al.*, 1991). Predicting a protein structure from sequence requires a link between 3D structure and 1D sequence. The program *VERIFY3D* provides this link by reducing a 3D structure to 1D string of environmental classes. Therefore the method can be used to evaluate any protein model or to measure the compatibility of any protein structure with its amino-acid sequence.

21.3.3.4. ERRAT

The program *ERRAT* (Colovos & Yeates, 1993) analyses the relative frequencies of noncovalent interactions between atoms of various types. It can be viewed as an extension of the earlier 3D profile approach from the residue level to the atom level. Three types of atoms are considered (C, N and O), and consequently six types of interactions are possible (CC, CN, CO, NN, NO and OO).

ERRAT operates under the hypothesis that different atom types will be distributed non-randomly with respect to each other in proteins due to complex geometric and energetic considerations, and that structural errors will lead to detectable anomalies in the pattern of interactions. Assessment of the non-bonded interactions is subject to the following restrictions: the distance between the two atoms in space is less than some preset limit, typically 3.5 Å, and the atoms within the same residue or those that are covalently bonded to each other are not considered. For each nine-residue segment of sequence, the non-bonded contacts to other atoms in the protein are tallied by atomic interaction type and the result is divided by the total number of interactions. This gives a list, or six-dimensional vector, of fractional interaction frequencies that add up to unity. In this way, each nine-residue fragment generates one point in a five-dimensional space; only five of the six fractional values are independent. A large number of observations were extracted from reliable high-resolution structures and used to establish a multivariate five-dimensional normal distribution for accurate protein structures. This distribution is used to evaluate the probability that a given

Detection of errors in the small subunit of ribulose-1,5-bisphospate carboxylase/oxygenase (RuBisCO). (*a*) *ERRAT* plot of the error function in a nine-residue sliding window, the centre of which is at the sequence position indicated by the horizontal axis. The solid bold line represents the revised structure and the dashed line the original structure. The thin solid lines indicate the 95% and 99% confidence limits for rejection. A region above the 95% line can be judged incorrect with 95% certainty. (*b*) *VERIFY3D* profile-window plots for the revised (bold) and original (dashed) models. The vertical axis gives the average 3D–1D score for residues within a 21-residue sliding window. Regions that score below zero are suspect. (*c*) Ramachandran diagram from *PROCHECK* of the initial structure of RuBisCO. The main-chain dihedral angle φ (N—Cα bond) is plotted *versus* ψ (Cα—C bond). All non-glycine residues outside the allowed regions are marked. (*d*) Ramachandran plot for the refined RuBisCO structure.

set of interactions from a protein model in question is correct. Since the *ERRAT* evaluation is based on a normal distribution calibrated on a reliable database, it is straightforward to estimate the likelihood that each region of a candidate protein model is incorrect. This method provides an unbiased and statistically sound tool for identifying incorrectly built regions in protein models.

21.3.4. Selection of database

Regardless of the specific approach or the specific criteria for validating structural models, a reliable reference database has to be chosen by careful selection of known structures. Suitable criteria to consider when selecting a database are: protein structures determined to resolutions of 2.5 Å or better, R factors less than 25%, and good geometry, particularly of the dihedral angles of the protein backbone. In addition, the database should include examples from many diverse classes of structures and at the same time avoid multiple identical structures.

21.3.5. Examples: detection of errors in structures

21.3.5.1. *Specific examples*

Several examples are presented of errors in structural models determined by X-ray crystallography that can be detected using validation methods. One is that of the small subunit of ribulose-1,5-bisphosphate carboxylase/oxygenase (RuBisCO), which was traced essentially backwards from a poor electron-density map (Chapman *et al.*, 1988). The program *ERRAT* finds that approximately 40% of the residues in this mistraced model are outside the 95% confidence limit (Fig. 21.3.5.1*a*). This limit is the error value above which a given region can be judged to be erroneous with 95% certainty, so a reliable model should exceed

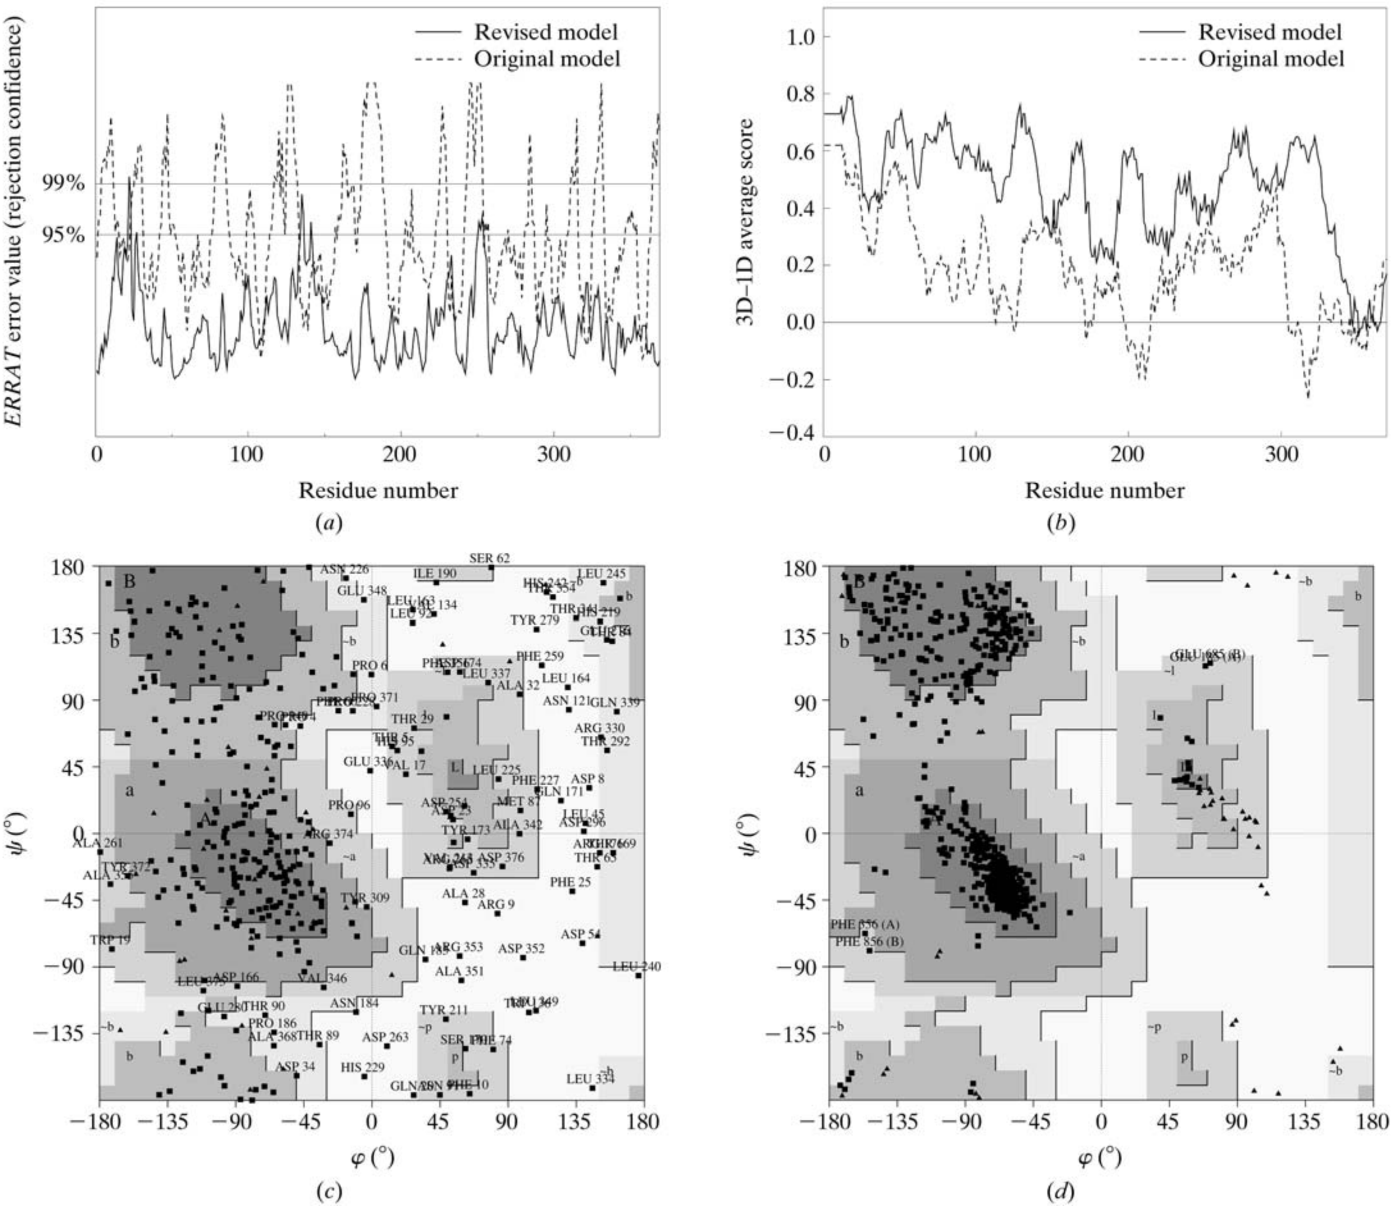

Figure 21.3.5.2
The detection of model errors due to refinement in an incorrect space group: an example (3xia.coor) from the archive of obsolete PDB entries. (*a*) *ERRAT* plot of the error function in a nine-residue sliding window. The solid bold line represents the revised structure and the dashed line represents the original structure. The thin solid lines indicate the 95% and 99% confidence limits for rejection. (*b*) *VERIFY3D* profile-window plots for the revised (bold) and original (dashed) models. The vertical axis gives the average 3D–1D score for residues within a 21-residue sliding window. (*c*) Ramachandran diagram of the original structure. All non-glycine residues outside the allowed regions are marked. (*d*) Ramachandran diagram for the revised structure.

this value over less than 5% of its length. The final model of RuBisCO (Curmi *et al.*, 1992) shows only 2% of the residues outside *ERRAT*'s 95% confidence limit. Similarly, the 3D profile calculated from *VERIFY3D* for the erroneous model (Fig. 21.3.5.1*b*) gives a total score of 15 when matched to the sequence of the small subunit of RuBisCO. This score is well below the expected value of 58 for the correct structure of this length. Indeed, the 3D profile of the correct model (Curmi *et al.*, 1992) (Fig. 21.3.5.1*b*) of RuBisCO has a score of 55. *PROCHECK* and *WHAT IF* also identify stereochemistry problems in the original model, including deviant bond angles and bond lengths, many residues in the disallowed Ramachandran regions (Fig. 21.3.5.1*c*), bad peptide-bond planarity, and bad non-bonded interactions. In contrast, most amino-acid residues of the correct RuBisCO model are in the allowed regions of the Ramachandran plot (Fig. 21.3.5.1*d*) with good overall geometry.

The archive of obsolete PDB entries maintained by the San Diego Supercomputer group (http://pdbobs.sdsc.edu) includes old versions of protein structures that have been withdrawn and/or replaced by the depositor with a newer version. One example is that of a protein (3xia.coor) originally solved to 3 Å in the wrong space group and later to 1.8 Å in the correct space group (1xya.coor). The *ERRAT* program reveals problems in the original model, with 45% of the residues outside the 95% confidence limit (Fig. 21.3.5.2*a*). The more recent model has only 1.5% of the residues outside the 95% confidence limit. The problem in the original model is also illustrated by the *VERIFY3D* plot (Fig. 21.3.5.2*b*) for which the average score is often below the value of 0.1 and dips below zero at four points. In contrast, the *VERIFY3D* plot of the revised model shows no dips below zero. Poor stereochemistry is also apparent in the Ramachandran plot of the original model (Fig. 21.3.5.2*c*). Only 38% of the backbone dihedral angles lie in the most favoured regions, compared to 93.8% in the revised model (Fig. 21.3.5.2*d*).

The potential usefulness of error-detecting programs during model building is suggested by stages in the crystal structure

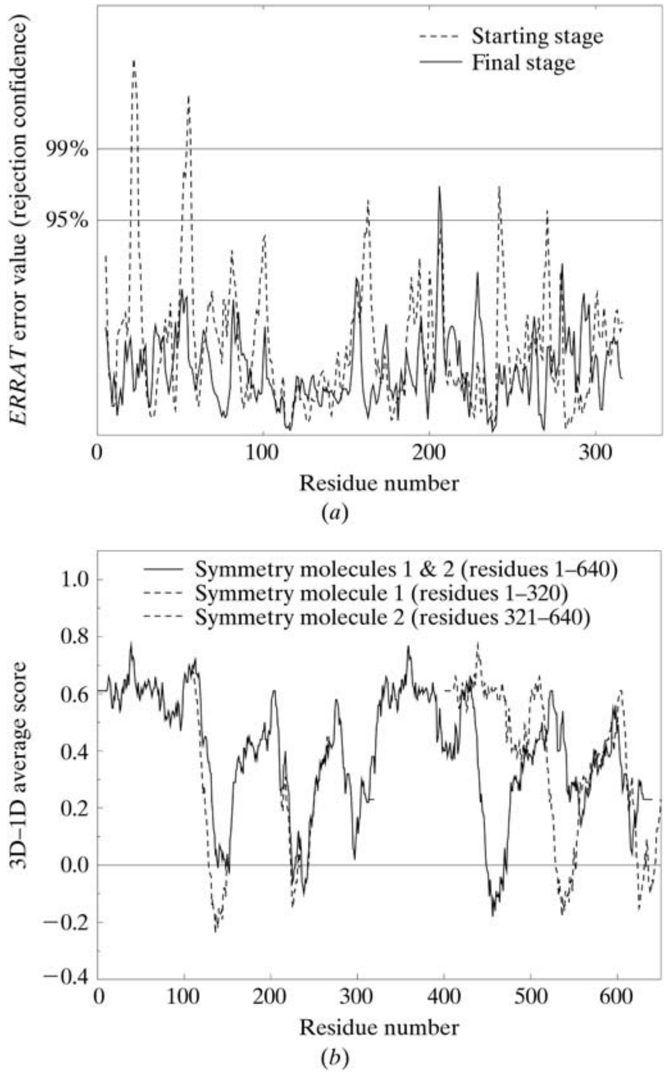

Figure 21.3.5.3
The usefulness of validation programs during model building is suggested by the example of the triacylglycerol lipase from *Pseudomonas cepacia* at different stages of atomic refinement. (*a*) Plot from *ERRAT* at the initial and final stages of refinement. (*b*) *VERIFY*3D profile-window plots of the final model. The dashed line represents symmetry molecule number 1 (residues 1–320) and symmetry molecule number 2 (residues 321–640) when not in contact with each other. The solid line represents symmetry molecule 1 and 2 when in contact. This plot illustrates that the state of oligomerization can affect the 3D profile plot, giving information on the oligomerization. See Bennett *et al.* (1994) for more details.

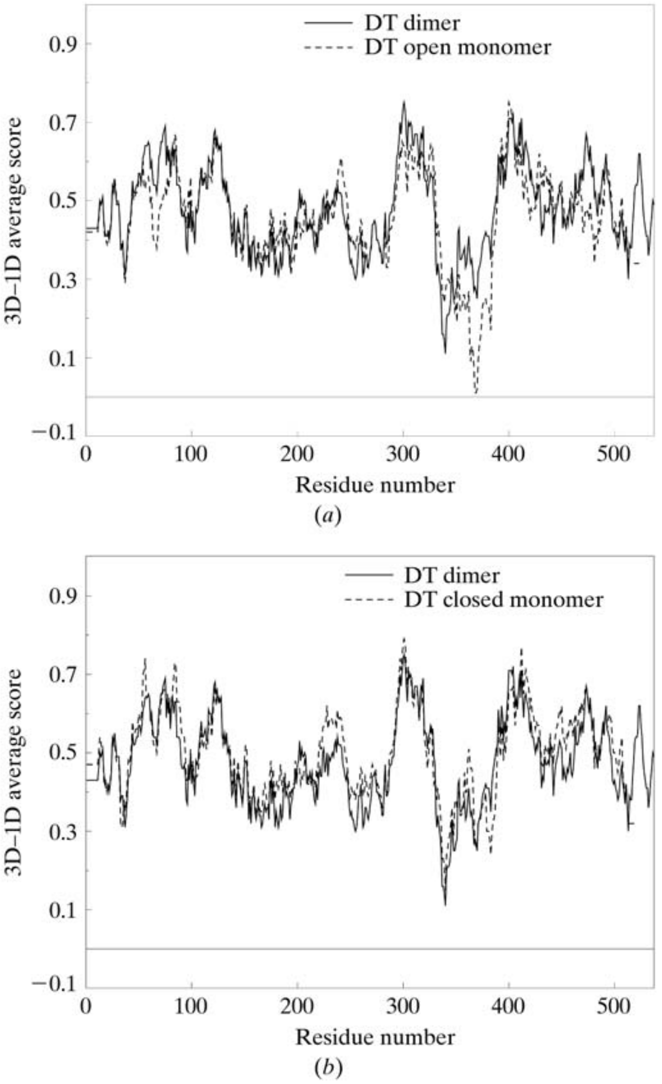

Figure 21.3.5.4
*VERIFY*3D profile plots of diphtheria toxin (DT) in three forms: open and closed monomers and the dimer. (*a*) DT open monomer (dashed), DT dimer (solid line). (*b*) DT closed monomer (dashed) and dimer (solid line). Notice that the hinge loop (residues 379–387) in the open monomer has a low profile score, and this structure is known to be unstable. The score is raised in the stable closed monomer and in the dimer.

determination of triacylglycerol lipase from *Pseudomonas cepacia* (Kim *et al.*, 1997), which was solved by MIR. The authors kindly provided us with ten different models (assigned as stage number 1–10) along the course of model building and refinement. Regions where Cα positions shifted between initial and final models correlated with regions where the error functions improved. For example, the program *ERRAT* points at specific regions (*e.g.* 18–35 and 135–165) originally assigned as poly-alanine. When at the next stage of refinement these were changed to the actual amino-acid sequence, these regions behaved normally (Fig. 21.3.5.3*a*). This illustrates that *ERRAT* is able to illuminate problem areas in a structure.

*VERIFY*3*D* is sensitive to unusual environments in proteins. An illustration is offered by the structures of lipases, with and without their inhibitors. There are two general conformations known as 'closed' and 'open'. In the so-called 'closed' structure, the catalytic triad is buried underneath a helical segment, called a 'lid' (Brzozowski *et al.*, 1991), so that hydrophobic residues tend to be buried as observed in a 'normal' 3D profile. In the 'open' conformation, the lipid binding site becomes accessible to the solvent, and hydrophobic surfaces (residues 140–150 and 230–250) are exposed by the movement of the 'lid'. These hydrophobic exposed regions are strikingly shown in the 3D profile of the 'open' structure (Fig. 21.3.5.3*b*), which clearly reveals the two problematic regions (140–150 and 230–250) with profile scores below zero. The exposed hydrophobic residues 140–150 from one symmetry model make van der Waals interactions with hydrophobic residues 230–250 from a symmetry-related molecule (Kim *et al.*, 1997). These interactions are revealed as higher scores in those regions when inspecting the 3D profiles of the two symmetry-related molecules.

Another example of unusual environment is that of diphtheria toxin (DT), which exists as a monomer as well as a dimer. Monomeric DT is a Y-shaped molecule with three domains known as catalytic (C), transmembrane (T) and receptor binding domain (R). Crystal structures have been determined for both the 'closed' monomeric form and for a domain-swapped dimeric form (Bennett *et al.*, 1994). Upon dimerization, a massive

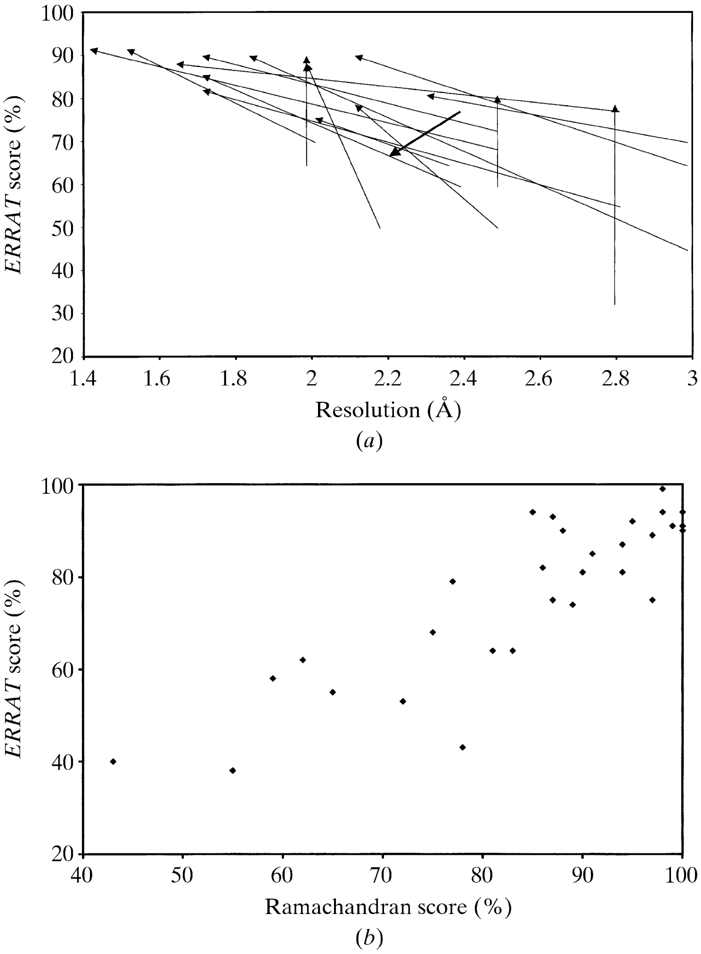

Figure 21.3.5.5
Evaluation of old and revised models in a database survey by *ERRAT*. (*a*) Percentage of residues within the 95% confidence limit given by *ERRAT* as a function of the resolution to which the structure was determined. Each arrow represents an obsolete structure (arrow tail) and the revised structure that replaced it (arrow head). The revised structures (typically analysed at finer resolution) show markedly improved *ERRAT* scores. (*b*) Correlation between the percentage of a structure within the 95% confidence limit according to *ERRAT*, and the percentage of residues in the most favoured regions of a Ramachandran diagram according to *PROCHECK*.

conformational rearrangement occurs and the entire R domain from each monomer of the dimer is interchanged with the other monomer. This involves breaking the noncovalent interactions between the R domain and the C and T domains and rotating the R domain by 180° with atomic movements up to 65 Å to produce the 'open' conformation. After rearrangement, each R domain reforms the same noncovalent interactions as it had in the monomer, but with the C and T domains of the other monomer. The existence of both open and closed forms of DT requires that large conformational changes occur in residues 379–387 (the hinge loop). The 3D profile of the 'open' form (Fig. 21.3.5.4*a*) shows low scores for these residues compared to the closed monomer or dimer (Fig. 21.3.5.4*b*). The higher scores of the open monomer are consistent with the greater stability of the monomer in the closed rather than the open conformation.

21.3.5.2. *Survey of old and revised structures*

The past two decades have seen a surge of development in the experimental techniques of crystal structure determination. As a consequence, many structures originally solved at low resolution were later determined at higher resolution, often starting with improved phases. The archive of obsolete PDB entries maintained by the San Diego Supercomputer group (http://pdbobs.sdsc.edu) served as a benchmark for evaluating the *ERRAT* program. For testing, 17 pairs of protein models were selected. Each pair comprised an obsolete entry and the revised model that replaced it. Using *ERRAT*, the overall quality of each model was expressed as a single number according to the fraction of the structure falling below the 95% confidence limit for rejection. The overall scores are significantly better for the revised structures, most of which were analysed at improved resolution (Fig. 21.3.5.5*a*). This result further demonstrates the utility of *ERRAT* for monitoring the model-building process. Furthermore, a strong correlation is found between the percentage of residues within the 95% confidence limit given by *ERRAT* and the percentage of residues in the most favoured regions of the Ramachandran plot of *PROCHECK* (Fig. 21.3.5.5*b*). In general, the problematic regions detected by the two programs agree with each other.

21.3.6. Summary

In order to ensure the quality of the growing protein structure databases, models must be evaluated carefully during and after the structure determination process. Model evaluation can incorporate two types of measures: agreement between the model and the experimental diffraction data, and agreement between the model and the database of known structures. The latter types use the atomic coordinates of the final model, but do not rely on the diffraction data. In recent years, powerful methods of this type have been developed.

The most informative and reliable model-evaluation criteria are those that measure properties not optimized as part of the automatic refinement procedure. The free *R* value has become important for monitoring the progress of atomic refinement for the same reason: it is based on reflections not included in refinement. We have focused here on two programs, *VERIFY3D* and *ERRAT*, which both evaluate high-level geometric properties not optimized during atomic refinement. Each offers the convenience of a single score over a sliding window along the protein sequence. Because *VERIFY3D* operates on the level of amino-acid residues, it is sensitive to errors on that scale, particularly those that affect the distribution of polar and nonpolar residues. *ERRAT* operates on the atomic level and has proven to be particularly useful for pinpointing local regions of protein models that require further adjustments. When used in combination, these methods and others can help crystallographers produce more accurate structural models of proteins.

21.3.7. Availability of software

The programs *ERRAT* and *VERIFY3D* are available on the World Wide Web for non-commercial applications. The URL for *VERIFY3D* is http://nihserver.mbi.ucla.edu/Verify_3D/ and the URL for *ERRAT* is http://nihserver.mbi.ucla.edu/ERRATv2/. *VERIFY3D* and *ERRAT* expect a coordinate file in PDB format. The programs return plots of the type shown in this chapter.

We thank Dr Kyeong Kyu Kim and Dr Se Won Suh of the Department of Chemistry, Seoul National University, Korea, for the models of triacylglycerol lipase. This work was supported by grants NIH GM 31299, DOE DE-FG03-87ER60615 and NSF MCB 9420769.

Chapter 21.4. *PROCHECK*: validation of protein-structure coordinates

R. A. Laskowski, M. W. MacArthur and J. M. Thornton

21.4.1. Introduction

As in all scientific measurements, the parameters that result from a macromolecular structure determination by X-ray crystallography (*e.g.* atomic coordinates and B factors) will have associated uncertainties. These arise not only from systematic and random errors in the experimental data but also in the interpretation of those data. Currently, the uncertainties cannot easily be estimated for macromolecular structures due to the computer- and memory-intensive nature of the calculations required (Tickle *et al.*, 1998). Thus, more indirect methods are necessary to assess the reliability of different parts of the model, as well as the reliability of the model as a whole. Among these methods are those that rely on checking only the stereochemical and geometrical properties of the model itself, without reference to the experimental data (MacArthur *et al.*, 1994; Laskowski *et al.*, 1998). Here we describe *PROCHECK* (Laskowski *et al.*, 1993), which is one of these structure-validation methods.

The *PROCHECK* program computes a number of stereochemical parameters for the given protein model and compares them with 'ideal' values obtained from a database of well refined high-resolution protein structures in the Protein Data Bank (PDB; Bernstein *et al.*, 1977). The results of these checks are output in easy-to-understand coloured plots in PostScript format (Adobe Systems Inc., 1985). Significant deviations from the derived standards of normality are highlighted as being 'unusual'.

The program's primary use is during the refinement of a protein structure; the highlighted regions can direct the crystallographer to parts of the structure that may have problems and which may need attention. It should be noted that outliers may just be outliers; they are not necessarily errors. Unusual features may have a reasonable explanation, such as distortions due to ligand binding in the protein's active site. However, if there are many oddities throughout the model, this could signify that there is something wrong with it as a whole. Conversely, if a model has good stereochemistry, this alone is not proof that it is a good model of the protein structure.

Because the program requires only the three-dimensional atomic coordinates of the structure, it can check the overall 'quality' of any model structure: whether derived experimentally by crystallography or NMR, or built by homology modelling. In the case of NMR-derived structures, it is useful to compare the protein geometry across the whole ensemble. An extended version of *PROCHECK*, called *PROCHECK-NMR*, is available for this purpose (Laskowski *et al.*, 1996), but will not be described here.

Note that *PROCHECK* only examines the geometrical properties of protein molecules; it ignores DNA/RNA and other non-protein molecules in the structure, except in so far as checking that the non-bonded contacts these make with the protein do not violate a fixed distance criterion.

21.4.2. The program

PROCHECK is in fact a suite of separate Fortran and C programs which are run successively *via* a shell script. The programs first 'clean up' the input PDB file, relabelling certain side-chain atoms according to the IUPAC naming conventions (IUPAC–IUB Commission on Biochemical Nomenclature, 1970), then calculate all the protein's stereochemical parameters to compare them against the norms, and finally generate the PostScript output and a detailed residue-by-residue listing. Hydrogen and atoms with zero occupancy are omitted from the analyses and, where atoms are found in alternate conformations, only the highest-occupancy conformation is retained.

The source code for all the programs is available at http://www.biochem.ucl.ac.uk/~roman/procheck/procheck.html. It has also been incorporated into the *CCP4* suite of programs (Collaborative Computational Project, Number 4, 1994) at http://www.dl.ac.uk/CCP/CCP4/main.html, and can be run directly *via* the web from the Biotech Validation Server at http://biotech.embl-ebi.ac.uk:8400/.

21.4.3. The parameters

Table 21.4.3.1 shows the principal stereochemical parameters used by *PROCHECK*, based on the analysis of Morris *et al.* (1992), who looked for measures that are good indicators of protein quality. The table shows the original parameters together with a more up-to-date set derived from a more recent data set including a number of atomic resolution structures (*i.e.* those solved to 1.4 Å resolution or better).

Table 21.4.3.1
Summary of expected values for stereochemical parameters in well resolved structures

Parameter	Old	New
% φ, ψ in core	>90.0%	>90.0%
χ_1 *gauche*$^-$	+64.1 ± 15.7°	+63.2 ± 11.4°
χ_1 *trans*	+183.6 ± 16.8°	+182.7 ± 13.1°
χ_1 *gauche*$^+$	−66.7 ± 15.0°	−66.0 ± 11.2°
χ_1 pooled standard deviation	±15.7°	±11.8°
χ_2 *trans*	+177.4 ± 18.5°	+177.2 ± 15.1°
χ_3 S—S bridge (left-handed)	−85.8 ± 10.7°	−84.8 ± 8.5°
χ_3 S—S bridge (right-handed)	+96.8 ± 14.8°	+92.2 ± 10.8°
Proline φ	−65.4 ± 11.2°	−64.6 ± 10.2°
α-Helix φ	−65.3 ± 11.9°	−65.5 ± 11.1°
α-Helix ψ	−39.4 ± 11.3°	−39.0 ± 9.8°
ω *trans*	+179.6 ± 4.7°	+179.5 + 6.0°
Cα—N—C$'$—Cβ (ζ) virtual torsion angle	+33.9 ± 3.5°	+34.2 ± 2.6°

For the most part, the parameters given in Table 21.4.3.1 are not included in standard refinement procedures and so are less likely to be biased by them. They can thus provide a largely independent and unbiased validation check on the geometry of each residue and hence point to regions of the protein structure that are genuinely unusual.

As more atomic resolution structures become available (Dauter *et al.*, 1997), these parameters will be improved. Because of their high data-to-parameter ratio, such structures can be refined using less strict restraints, and hence contain a smaller degree of bias in their geometrical properties – at least for the well ordered parts of the model. Such information moves us a step closer to an understanding of the 'true' geometrical and

Copyright © 2012 International Union of Crystallography

conformational properties of proteins in general and, one day, the target parameters will be derived exclusively from such structures.

PROCHECK also checks main-chain bond lengths and bond angles against the 'ideal' values given by the Engh & Huber (1991) analysis of small-molecule structures in the Cambridge Structural Database (CSD) (Allen *et al.*, 1979). Unlike the above parameters, these geometrical properties are usually restrained during refinement, and, furthermore, the Engh & Huber (1991) targets are the ones most commonly applied. Thus analyses of these values merely reflect the refinement protocol used and do not provide meaningful indicators of local or overall errors. However, the plots clearly show any wayward outliers which can nevertheless indicate problem regions in the structure.

21.4.4. Which parameters are best?

Possibly the most telling and useful of the 'quality' indicators for a protein model is the Ramachandran plot of residue φ–ψ torsion angles. This can often detect gross errors in the structure (Kleywegt & Jones, 1996*a*,*b*). In the original Ramachandran plot (Ramachandran *et al.*, 1963; Ramakrishnan & Ramachandran, 1965), the 'allowed' regions were defined on the basis of simulations of dipeptides. In the *PROCHECK* version, the different regions of the plot are defined on the basis of how densely they are populated with data points taken from a database of well refined protein structures. The regions are: core, allowed, generously allowed and disallowed.

The 'core' regions are particularly important; the points on the plot tend to converge towards these regions, and to cluster more tightly within them, as one goes from structures solved at low resolution to those solved at high resolution (Morris *et al.*, 1992). This trend has recently been confirmed by Wilson *et al.* (1998), who looked at the case of atomic resolution structures. It has also been analysed in terms of 'attractors' at the most favourable regions of the plot; as the resolution improves, so the points are drawn towards these attractors (Walther & Cohen, 1999).

Fig. 21.4.4.1 shows the original *PROCHECK* Ramachandran plot and a more up-to-date version. The original was based on all 462 structures known at that time (1989/90), while the more recent one, generated in 1998, is based on 1128 non-identical (*i.e.* having a sequence identity <95%) structures. It can be seen that the second plot has core regions which are much tighter than the original, and this is primarily due to the increase in the number of very high resolution structures giving a more accurate representation of the tight clustering in the most favourable regions.

Another parameter that seems to be a particularly sensitive measure of quality is the standard uncertainty (s.u.) of the χ torsion angles. Morris *et al.* (1992) found that the average values of a protein's χ_1 and χ_2 torsion angles are well correlated with the resolution at which the protein structure was solved. Although the data set was a fairly small one, the conclusion was borne out when tested on a larger set of more recent structures, including some solved to atomic resolution (Wilson *et al.*, 1998). This measure, however, cannot be relied on where side-chain conformations are either restrained or heavily influenced by the use of rotamer libraries.

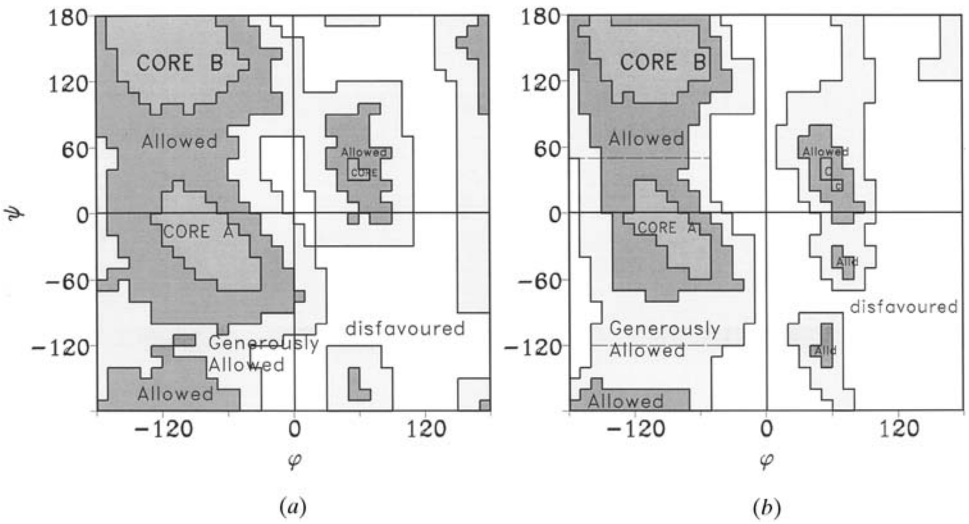

Figure 21.4.4.1
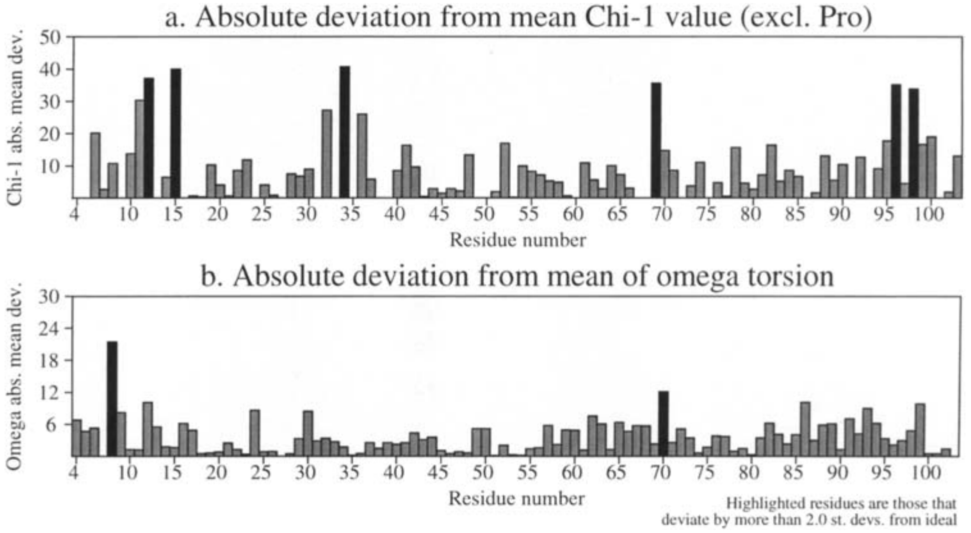
PROCHECK Ramachandran plots showing the different regions, shaded according to how 'favourable' the φ–ψ combinations are, for (*a*) the original version of the program (1992) and (*b*) an updated version based on a more recent data set (1998) including more high-resolution structures. The 'core' and other favourable regions of the plot are more tightly compressed in the new version, with the white, disfavoured regions occupying more of the space.



a. Absolute deviation from mean Chi-1 value (excl. Pro)

b. Absolute deviation from mean of omega torsion

Highlighted residues are those that deviate by more than 2.0 st. devs. from ideal

Figure 21.4.6.1
Two of the residue-property plots generated by *PROCHECK*. The plots shown here are (*a*) the absolute deviation from the mean of the χ_1 torsion angle (excluding prolines) and (*b*) the absolute deviation from the mean of the ω torsion angle. Usually, three such plots are shown per page and can be selected from a set of 14 possible plots. On each graph, unusual values (usually those more than 2.0 standard deviations away from the 'ideal' mean value) are highlighted.

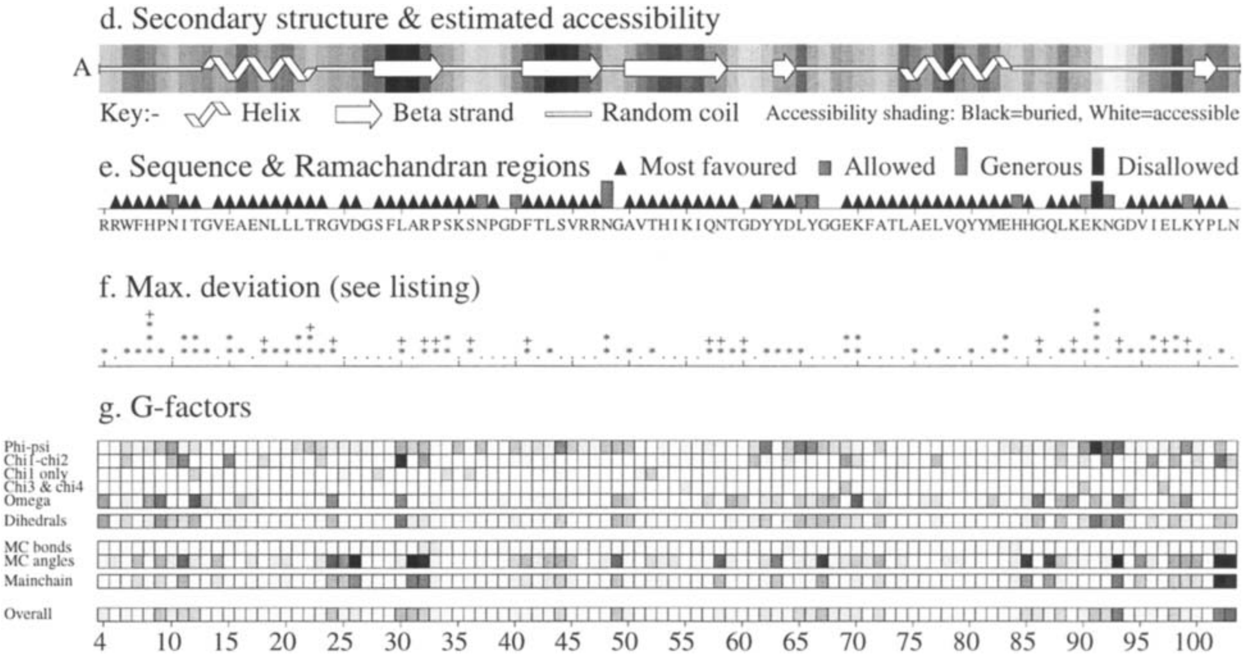


Figure 21.4.6.2

Schematic plots of various residue-by-residue properties, showing (*d*) the protein secondary structure, with the shading behind it giving an approximation to each residue's accessibility, the darker the shading the more buried the residue; (*e*) the protein sequence plus markers identifying the region of the Ramachandran plot in which the residue is located; (*f*) a histogram of asterisks and plus signs showing each residue's maximum deviation from one of the ideal values, as shown on the residue-by-residue listing; and (*g*) the residue '*G* factor' values for various properties, where the darker the square the more 'unusual' the property.

21.4.5. Input

The primary input to *PROCHECK* is the file containing the 3D coordinates of the protein structure to be processed. The file is required to be in PDB format. An additional input file is the parameter file that governs which plots are to be generated and deals with certain aspects of their appearance.

21.4.6. Output produced

The output of the program consists of a number of PostScript plots, together with a full listing of the individual parameter values for each residue, with any unusual geometrical properties highlighted. The listing also provides summaries for the protein as a whole. Figs. 21.4.6.1 and 21.4.6.2 show parts of one of the PostScript plots generated, showing the variation of various residue properties along the length of the protein chain. Unusual regions, which are highlighted on these plots, may require further investigation by the crystallographer.

21.4.7. Other validation tools

PROCHECK is merely one of a number of validation tools that are freely available, some of which are mentioned elsewhere in this volume. The best known are *WHATCHECK* (Hooft *et al.*, 1996), *PROVE* (Pontius *et al.*, 1996), *SQUID* (Oldfield, 1992) and *VERIFY3D* (Eisenberg *et al.*, 1997). Tools such as *OOPS* (Kleywegt & Jones, 1996*b*) or the X-build validation in *QUANTA* (MSI, 1997) provide standard tests on the geometry of a structure and provide lists of residues with unexpected features, which make it easy to check electron-density maps at suspect points.

Significant contributors to the programs in the *PROCHECK* suite include David K. Smith, E. Gail Hutchinson, David T. Jones, J. Antoon C. Rullmann, A. Louise Morris and Dorica Naylor. Part of the development work was funded by a grant from the EU Framework IV Biotechnology programme, contract CT96–0189.

Chapter 21.5. *KiNG* and kinemages

V. B. Chen, J. S. Richardson and D. C. Richardson

21.5.1. Introduction to aims and concepts

KiNG and the kinemages it displays provide molecular graphics, organized in an unusual way, that are of interest to crystallographers for uses that range from interactive illustrations for teaching and web display, to high-dimensional data display, to a dot-surface representation of all-atom van der Waals contacts, updated in real time by *Probe* to help guide model-to-map fitting.

A kinemage ('kinetic image') is an authored interactive three-dimensional illustration that allows open-ended exploration but has viewpoint, explanation and emphasis built in. A kinemage is stored as a human-readable flat ASCII text file that embodies the data structure and three-dimensional plotting information chosen by its author or user. The original kinemage viewer, *Mage* (Richardson & Richardson, 1992, 1994), is a pure graphics display program designed to show and edit kinemages, while *Prekin* constructs molecular kinemages from PDB (Protein Data Bank; Berman *et al.*, 2000) files. A spiritual successor to *Mage*, *KiNG* (Kinemage, Next Generation) is a Java-based kinemage reader (Chen *et al.*, 2009) and has evolved into a fully featured alternative to *Mage*. *KiNG* includes a Java program *Molikin*, based heavily on *Prekin*, to construct kinemages from PDB files or mmCIF files. The latest versions of *KiNG*, *Mage* and *Prekin* are available free and open source for Macintosh, PC or Linux from the kinemage web site (http://kinemage.biochem.duke.edu).

KiNG and *Mage* operate quite equivalently on the different platforms, and their graphical interfaces differ very little except where each has some unique feature for construction, drawing or modelling. All the major features of *KiNG* described here are also available in *Mage*, except for the 'backrub' tool (Davis *et al.*, 2006) and the web online display. *KiNG* has more convenient tools for superposition, electron-density display and built-in kinemage construction, while *Mage* has a number of historical tools for highly specialized purposes, such as a system for defining separate groups with rotatable bonds (such as an RNA suite or a ligand), and the ability to time, score and save exercise or test results. By policy, later versions of *Mage* can display all older kinemages back to 1992, and *KiNG* comes very close. This means that the kinemage format has standard forms but also recognizes many alternative forms likely to occur in human-edited files or those produced by other software (such as 'gray' *versus* 'grey', and commas, spaces or line breaks as field separators).

By design, *KiNG* has no internal knowledge of molecular structure (except for a few built-in libraries used for mutations and rebuilding). A collaboration between the author and the authoring program (*e.g. Molikin*) builds data organization into the kinemage itself. This two-layer approach has great advantages in flexibility, since an author can show things the programmer never imagined, including non-molecular three-dimensional relationships. Overall, just viewing kinemages demands less work and less expertise from the reader than most molecular graphics, but that ease of use depends on the authoring effort involved in making thoughtful choices, aided by the extensive on-screen editing capabilities described below.

Mage and *KiNG* are both designed to optimize visual comprehension: the understanding and communication of specific three-dimensional relationships inside complex molecules. Display speed has been given priority, to ensure good depth perception from smooth real-time rotation, even for a whole ribosome. The interface is extremely simple and transparent, and the colour palette has been carefully tuned for visual comparisons, contrasts and depth cueing. Immediate identification and measurement are always active; views, animations or bond rotations can be built in by the kinemage author. A text window explains the intentions of the author, while a simple hypertext capability allows the reader to jump to the specific view and display objects being described; however, most kinemages can also be successfully understood just by exploring what is available within the graphics window.

Kinemages are suitable for structure browsing or producing static two-dimensional presentation graphics, but those aspects have been kept secondary to effectiveness for interactive visualization and flexibility of author specification. Features and representations have deliberately been chosen to be fast and simple but spatially informative, rather than either showy or traditional, as illustrated by the following examples and their rationales. Mouse-controlled rotation in *KiNG* depends only on the direction of drag, so that the behaviour of the image is independent of absolute cursor position within the window. Labels are available but seldom needed, since the data structure builds in a 'pointID' that is displayed whenever the point is picked. Instead of half-bond colouring, which tends to chop up the image, *Molikin* by default provides separate colours and button controls for main chain *versus* side chains, and it can prepare a partial 'ball & stick' representation with colour-coded balls on non-carbon, non-hydrogen atoms (see Fig. 21.5.1.1). Hydrogen atoms are crucial for some research uses, but to minimize the clutter from twice as many atoms, *Molikin* sets up their display under button control. For effective perception of conformational change, while avoiding either the confusion of overlays or the potential misrepresentation of computed interpolation, *KiNG* features simple animation switching between known conformations. Very importantly, since molecular information resides mostly in chemical bonds and spatial proximity, kinemages emphasize fully three-dimensional representations, such as vectors, dots or balls, rather than surface graphics that obscure internal structure. A space-filling representation (the 'spherelist') is available, but it is suggested that it be used very sparingly – for example, to show the size and shape of a small-molecule ligand. If an extensive surface is needed, a dot surface is more informative, since the underlying atoms and bonds can be seen at the same time. However, a well rendered ribbon is unmatched for conveying overall 'fold'. *Molikin* calculates and *KiNG* displays spline-smoothed ribbon schematics similar to the original hand-drawn style (Richardson, 1981), with black-line edges to aid depth perception (see Fig. 21.5.1.1*a*). For interactive use they serve first as introduction to a structure, and then as context for more detailed ball, vector and dot representations.

Copyright © 2012 International Union of Crystallography

For kinemages, the representation style is not a global choice that applies to everything shown, but rather is a set of local options (varied across space or sequence) chosen to provide appropriate emphasis and comprehensible detail within context.

21.5.2. Uses of *KiNG* and kinemages

21.5.2.1. Use as a reader of existing kinemages

Viewing a pre-existing kinemage file requires almost no learning process: the interface is sufficiently 'transparent' that interaction is mainly with the molecule rather than with the program (Richardson & Richardson, 2002). Six simple operations cover all basic functionalities: (1) drag with the mouse to rotate the displayed object; (2) click on a point to identify it; (3) turn things on or off, or animate if that option is present, with labelled buttons; (4) choose preset views from the Views pull-down menu; (5) read the author's explanations in the text window; and (6) change to the next kinemage in the file with the Kinemage selection list on the upper right corner of the GUI. At a slightly more complex level, one can recentre, zoom the scale, move the clipping planes and save a view; measure distances, angles and dihedrals or 'Find' by point name (from the Edit pull-down menu); change Display menu options such as stereo or perspective; or consult the Help menu. There are keyboard shortcuts for convenience (such as 'a' to animate or 'c' for cross-eye *versus* wall-eye stereo), but they are never the only method and they are defined on the menus.

21.5.2.2. Use for teaching and on the web

Simplicity of interface, free cross-platform availability and attention to presentation issues (such as a keystroke to make labels and measures large and visible for an audience) make *KiNG* and kinemages especially well suited for teaching and learning about macromolecular structure or about crystallographic concepts such as handedness and symmetry. Teachers can use, adapt or create kinemage materials for class- or homework, on the computer or on paper (*e.g.*, file HbAllo.kin on haemoglobin). Interactively evaluated exercises (such as HBondPractice.kin) or timed tests (such as 3Dlit2atst.kin) can be set up in *Mage*. Especially valuable is student construction of reports or projects in kinemage format using *KiNG*, which they find increases their structural understanding and we find lets us evaluate that understanding. Suggestions can be found in Richardson & Richardson (2002) and examples, documentation and links to other kinemage web sites and materials can be found under Kinemages or under Teaching, at the kinemage web site http://kinemage.biochem.duke.edu.

KiNG has a number of options for making illustrations, including direct two-dimensional output of the current graphics window (at enhanced resolution) to JPEG, PNG or PDF image formats, or to POV-Ray for rendering. Movies can be made in *KiNG* of rotation, motion or changes, and either those or the static two-dimensional images can be inserted into PowerPoint-style presentations. Direct use of interactive three-dimensional graphics on the web without need for user installation [as is central to our *MolProbity* (Davis *et al.*, 2007; also Chapter 21.6 of this volume) structure-validation web service] was a major motivation for writing *KiNG* in Java. That same convenience can enhance web materials for courses or the presentation of structural results on a laboratory web site. Examples and simple templates in html are given on the kinemage web site under Software/KiNG.

21.5.2.3. Use for research

For general molecular-structure studies, kinemages act as a three-dimensional laboratory notebook where author and reader are the same person. These kinemages keep a visual record of the

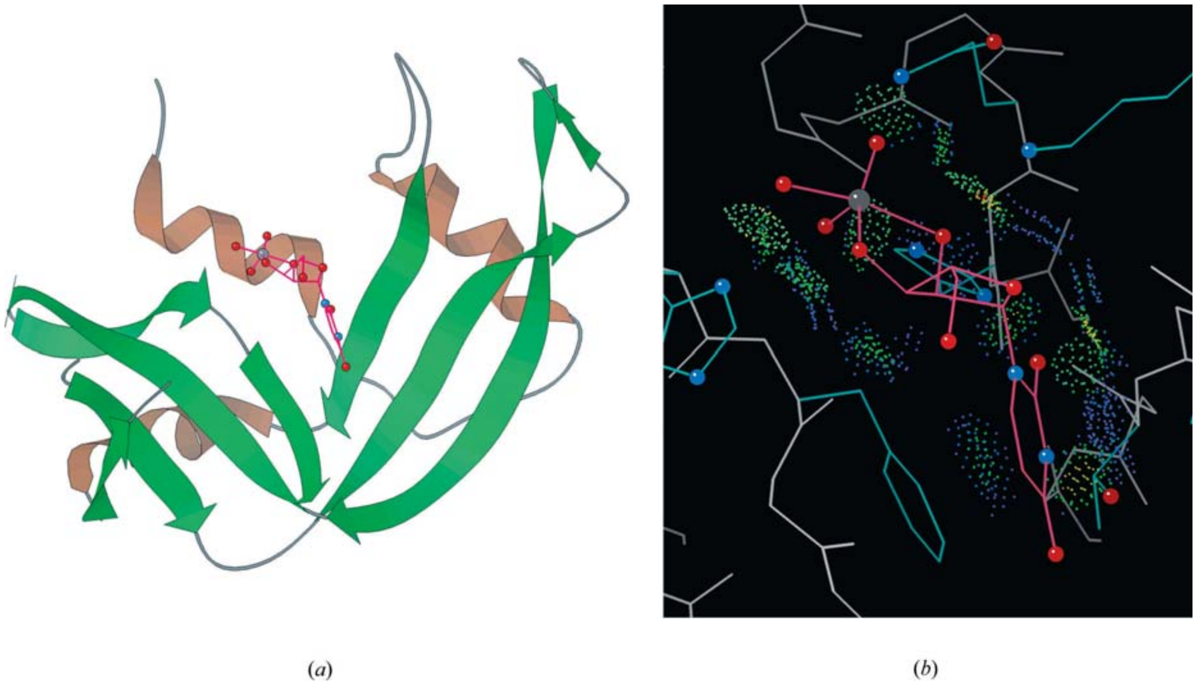

Figure 21.5.1.1
Illustration of combining molecular representations in kinemage format, shown in *KiNG*. (*a*) shows a ribbon schematic of the uridine vanadate–ribonuclease A complex at 1.3 Å resolution (PDB code: 1RUV) (Ladner *et al.*, 1997), with the bound inhibitor in ball representation. (*b*) shows a close up of the binding pocket, with the contacting side chains (cyan) and backbone (white) of the enzyme as vectors, the uridine vanadate as balls, and all-atom contacts at the enzyme–inhibitor interface as drawn by *Probe*; hydrogen bonds are pillows of pale green dots, favourable van der Waals contacts are outlined by blue, green and yellow dots, and there are no steric clashes.

Screenshot of *KiNG* presenting interactive three-dimensional validation data directly in the browser, in a *MolProbity* session for PDB code 2C0Q (Ekstrom *et al.*, 2006), a better-than-average 2.5 Å resolution structure. On the Cα backbone (white) all validation outliers are shown: clashes as clusters of hot-pink spikes, Ramachandran outliers in green, rotamer outliers as gold side chains and Cβ deviations as magenta spheres; no bond-length or angle outliers are visible. The user can centre, zoom in and turn on all atoms to study a given problem in detail.

research process with selections, views, labels, measurements, superpositions *etc.*, plus a descriptive record in the text window. On-screen editing tools allow easy deletion of unwanted parts, constructions such as ring centres or helix axes and measurements on them, drawing shortened or dotted lines, recolouring or dragging points or regions, and many other operations in addition to the molecular rebuilding described below.

Setting up an animation between conformations or between related structures is an easy and very sensitive way of seeing changes, including correlated motions. Completely new display objects and organizations can be added to kinemages, such as three-dimensional plots of related non-molecular data. Kinemages are an easy and platform-independent way of sharing ideas with collaborators, either side-by-side or at a distance with simultaneous discussion, or just by sending a kinemage with its preset views and notes. [This is easy enough that a co-laboratory function through socket connection in *Mage* has rarely been used, and was therefore not implemented in *KiNG*.] Later, the working research kinemages can be used to produce either static two-dimensional or interactive illustrations for lectures or publication.

KiNG has been useful for displaying data other than molecular structure, however, since the kinemage format is a generic plotting format, not tied to display of molecules. For instance, the *MolProbity* structure validation web server (Davis *et al.*, 2007; Chen *et al.*, 2010; Chapter 21.6) generates two-dimensional Ramachandran data plots and three-dimensional Cβ deviation scatter plots which can be downloaded and viewed in *KiNG*. In addition, support for higher-dimensional data has been added to *Mage* and *KiNG*. For high-dimensional kinemages, the user chooses on the fly which three dimensions to display at a time. Also, a parallel-coordinate view (Inselberg, 1985) is available with a single keystroke, which displays the multiple axes as a series of parallel lines and each multi-dimensional point as a poly-line across those axes. With this combination of features, users can track, colour and measure the behaviour of clusters of points in many dimensions. Seven-dimensional kinemage analysis was particularly instrumental in defining full-detail RNA backbone conformers (Richardson *et al.*, 2008).

Two important tools for assessing the quality of structures are *Probe* and *Reduce*. *Probe* analyses molecular interactions by calculating small-probe contact dots wherever two atoms are within 0.5 Å of van der Waals contact (Word, Lovell, LaBean *et al.*, 1999), for numerical scoring or for display in *KiNG* (Fig. 21.5.1.1*b*), where the three types of contacts (hydrogen bonds, favourable van der Waals contacts and unfavourable 'clash' overlaps) are under separate control. All-atom contact analysis requires all hydrogen atoms; they are added by *Reduce* (Word, Lovell, Richardson & Richardson, 1999; Davis *et al.*, 2007), which optimizes the orientations of OH, SH and NH_3 groups, and possible 180° flips of Asn, Gln or His side-chain ends, considering both van der Waals clashes and hydrogen bonds analysed combinatorially in local networks. These contact-surface tools have research uses that fall into two distinct categories: one is study of the patterns and causes of particular structural features in molecules (best done on atomic resolution structures; Fig. 21.5.1.1*b*); the other is sensitive testing, validating and adjusting of an individual molecular model, either computational or experimental (exemplified by the *MolProbity* validation analysis).

Figure 21.5.2.2
Screen capture of side-chain rebuilding in *KiNG* using the side-chain rotator and backrub tools, with display of electron density, all-atom contacts and rotamer quality. In this example from the 1.1 Å resolution crystal structure of the calponin homology domain of β-spectrin (PDB code: 1BKR) (Banuelos *et al.*, 1998), a threonine was fitted with its side chain flipped over by 180°. The original (in gold since it is a rotamer outlier) has large bond-angle outliers and steric clashes, and its Cβ is entirely out of density. Using the side-chain rotator tool in combination with the backrub tool allows a much better fit to the density (the thicker orange 'mobile' side chain), with an excellent rotamer, ideal geometry and two hydrogen bonds (pale green dot pillows) for the Thr OH. H atoms and van der Waals dots are turned off, for clarity in two dimensions.

21.5.2.4. *Cystallographic rebuilding tools*

In crystallography, the most important use of all-atom contact analysis is for quickly finding, and frequently for fixing, problems with molecular geometry during fitting and refinement. All-atom contacts add independent new information to that process, since the hydrogen atoms make almost no contributions either to the electron density or to the energetic component of refinement as presently done, yet they are undeniably present and cannot significantly overlap other atoms (except in hydrogen bonds). The steric constraints implied by all-atom contacts are significantly more stringent than those based only on non-hydrogen atoms, yet they are obeyed almost perfectly by low-*B* regions of structures at resolutions near 1 Å, even when hydrogen atoms were not used in refinement.

At any stage of a structure determination, contact dots for the entire molecule or molecules can be calculated by *Probe* and examined in *KiNG*, or a list of the severe clashes and other outliers can be generated, for printout or as a scripted 'to-do' list for rebuilding in *Coot* (Emsley & Cowtan, 2004; Emsley *et al.*, 2010).

The most common way to do *MolProbity* analysis on a structure is on the web site (http://molprobity.biochem.duke.edu) (Davis *et al.*, 2007; Chen *et al.*, 2010; Chapter 21.6), which guides the entire process through to both chart and kinemage analysis of the local quality of a macromolecular structure. The resulting 'multi-criterion' kinemage flags all the individual outliers on the three-dimensional structure (Fig. 21.5.2.1): serious clashes ($\geq$0.4 Å overlap), poor side-chain rotamers, backbone bond-length or angle outliers, Cβ deviations, Ramachandran outliers and, for RNA, sugar-pucker and backbone conformer outliers (Richardson *et al.*, 2008). That kinemage can be viewed in *KiNG* online, but for rebuilding to correct the diagnosed problems a user would download the multi-criterion kinemage and the H- and flip-optimized PDB file for off-line work in *KiNG*. The multi-criterion kinemage shows where work is needed. However, the most powerful use of all-atom contact information is directly and interactively in the process of fitting and rebuilding. Therefore, the rebuilding tools in *KiNG* can call *Probe* on-the-fly during refitting, for display of clashes, hydrogen bonds and favourable van der Waals contacts (as well as updated rotamer quality and checks for φ, ψ and τ outliers) (Lovell *et al.*, 2000, 2003). This gives instant feedback on how user-proposed changes improve or worsen the model locally. These tools, including a side-chain mutation tool, a side-chain rotator tool, a backrub tool and an RNA rotator tool for adjusting RNA suite conformations, read in PDB files (with H atoms) and save all user modifications directly to PDB format files, for ease of use with other refinement or analysis programs. *KiNG* can also read in and display most common formats of electron density or difference density files, which are essential to the rebuilding process. Side chains are by default added in ideal geometry and in a choice of ideal rotamers, with user adjustment of torsion angles from there. The 'backrub' motion (Davis *et al.*, 2006) is a subtle rotation of the dipeptide, shown to occur frequently in protein molecules and especially valuable in side-chain modelling because of its leverage on the Cα–Cβ orientation. Fig. 21.5.2.2 shows an example of the side-chain rotator, backrub and real-time contact tools in action.

A number of other commonly used crystallographic tools have been modified to use *Probe* and *Reduce* as well. Historically, both *O* (Jones *et al.*, 1991) and *XtalView* (McRee, 1999) included some facility for all-atom *Probe* analysis. *Coot* (Emsley & Cowtan, 2004; Emsley *et al.*, 2010) can call *Reduce* and *Probe* directly, displaying hydrogens and all-atom contact dots during refitting. Also, *MolProbity* can write a scheme or Python input script for *Coot* which produces a list of labelled buttons that take the *Coot* user to each residue with a *MolProbity*-diagnosed clash, Ramachandran or rotamer outlier. Most notably, all *MolProbity* evaluations are available in *Phenix* (Adams *et al.*, 2010), with display in *KiNG* and interactive links for outlier corrections in *Coot*.

In *KiNG* or in these other systems, using all-atom contact display during refitting often makes conformational choices unambiguous, even when the electron density alone does not distinguish them. This criterion can locate a Met methyl, find the correct orientation for the final branch of an Asn or Gln, or a Thr, Val or Leu, improve the backbone conformation of a Gly, disentangle alternate conformations, or show which direction a ligand binds, all at a lower resolution than otherwise possible.

Side-chain rebuilding in *KiNG* is also very effective for analysing the suitability and probable effect of single-site mutations or redesigns (*e.g.* Ghaemmaghami *et al.*, 1998; Grell *et al.*, 2000; Wales *et al.*, 2004; Humphris & Kortemme, 2008). That effectiveness depends on the interactive update of rotamer quality and all-atom contacts, and is enhanced by use of the backrub motion, originally in *KiNG* and now also in *Coot* and several protein design systems (Georgiev *et al.*, 2008; Smith & Kortemme, 2008).

21.5.3. Making kinemages

There are numerous methods of creating kinemages. At the most basic level, users can hand-type a set of three-dimensional coordinates into a text file, adding only a small amount of hierarchical organization, and then view the data. Both *KiNG* and *Mage* by policy are very tolerant to parsing alternatives, minor mistakes and missing objects within a kinemage; so as long as an input file is reasonably close to being correct, something will still be displayed. Naturally, though, for large amounts of data, hand-creation of kinemages is impractical, so for viewing three-dimensional (or higher-dimensional) statistical data, *KiNG* includes a 'Data plotter' tool which will read in a delimited spreadsheet text file and automatically create a high-dimensional kinemage from those data.

For creating kinemages from PDB or mmCIF files, *KiNG* has several options. *Molikin* allows *KiNG* to read PDB or mmCIF files directly from the command line, with a small number of command-line flags for specifying some of the most common kinemage options, including ribbons or 'lots' (which produces vectors for the main chain, side chains, hydrogen atoms and non-water heterogens, small balls for waters, and pointIDs that include *B* factors). In the *KiNG* GUI, the 'Import' tool in the File menu provides access to *Molikin* features as well. For quick browsing of structure files, drag-n-drop or the 'Import' → 'To quick kin' menu allows users to quickly import and construct kinemages, similar to the command-line options. For more direct control of the options shown in the kinemage, the 'Import'→ 'Molecules' option brings up the *Molikin* GUI, which allows users to choose precisely what is shown. Users can specify what models, chains, residues, side-chain types and atoms to show, in a variety of representation types.

The many modes and options make *KiNG* and kinemages useful for a myriad of purposes, in addition to simple structure browsing. Making a kinemage for research, teaching, publication or distribution is an iterative and deliberate process. While the built-in kinemages provide a good starting point, finding the optimal colours, views and objects to display can be time consuming. *KiNG* includes a number of built-in on-screen editing tools which make this task easier.

On-screen editing of a kinemage in *KiNG* usually begins with setting up a few good views: rotate, pick centre, zoom and clip to optimize each one, and save it with 'Save current view' on the Views pull-down menu; it then shows up on the same menu with the given label. For editing of object properties in the kinemage, the 'Edit/draw/delete' tool in the Tools menu brings up a separate toolbox containing a variety of editing tools. These options, once selected, utilize mouse clicks in the graphics window to determine the objects that are modified, often with additional options that only appear when the particular option is selected. For example, the 'Paint points' option brings up a colour selection drop-down list, as well as a selection-type list. By default, the 'Paint points' option allows users to paint all the points that appear within a circle, which is drawn in the GUI window to allow users to see precisely what they are painting before they actually paint. A variety of drawing and deletion tools are also included in the 'Edit/draw/delete' tool. 'Edit text' (Edit menu) brings up the text window, which allows explanations to be included with the kinemage. Several superposition or docking tools, at varying levels of complexity, allow the user to move one molecule or group onto another similar one, for comparison or animation.

KiNG includes a built-in 'Internal palette' kinemage (in the Help menu) which shows the kinemage palette of colours with their names and gives some guidelines for choosing effective colours. The palette includes emphasis colours (green, yellow, hot pink), low-emphasis colours (purple, brown), pastels and a large variety of mid-tones (such as gold, peach, lilac), with a depth-cueing formula that ensures smooth change and maintenance of the perceptual colour value at all depths. In *KiNG*, if the built-in palette does not suffice, the user can create custom HSV (hue, saturation, value) colours. The default black background works best on the computer screen or for lecture-hall projection, but a white-background mode with a modified palette is available when needed for printed images (*e.g.* Fig. 21.5.1.1*a*) or for projection in high-ambient-light conditions.

Context is important for a kinemage (usually at least overall C$^{\alpha}$'s) but often it is helpful to delete features that are not directly relevant to the current interest (*e.g.* Fig. 21.5.1.1); therefore *KiNG* includes a versatile set of deletion tools (punch, prune, auger, spherical crop). This selection process is like the simplification and emphasis needed for a good two-dimensional illustration, but in this case it applies to the fully interactive three-dimensional form. For a kinemage, however, it is both possible and advantageous to include some additional details for further exploration, controlled by a button which can start out turned off.

At any stage of kinemage editing, a text editor can be used to look at the plain ASCII kinemage file, with its text, its views, and the hierarchy of group, subgroup and list display objects in human-readable and clearly identified forms. Lists (*e.g.* @vectorlist {name}) can be of vectors, dots, labels, words, balls, spheres, triangles or ribbons. Any part of the file can be edited, using its existing format as a guide or looking at another kinemage file that provides a desired template. The formal rules are described in format-kinemage.pdf, linked from Software/KiNG on the kinemage web site. One of the few operations that currently must be edited outside rather than inside *KiNG* is moving points between different lists (for instance, setting up a new list of just active-site side chains in a different colour and controlled by their own button). After editing a file outside *KiNG*, the kinemage should be saved without formatting, as a plain text file.

All in all, making a simple kinemage is trivial, but making really good ones for use by others is much like making a good web page. There are tools that make the individual steps easy, but one needs to exercise restraint to keep it simple enough to be both fast and comprehensible, patience to keep looking at the result and modifying it where needed, and judgment about both content and aesthetics.

21.5.4. Software notes

Mage and *Prekin* were written in C by David C. Richardson. *KiNG* and *Molikin* were written in Java by Ian W. Davis and Vincent B. Chen with contributions by Daniel A. Keedy, and are compatible with any Java 1.5+ equipped system. *Probe* (in C) and *Reduce* (in C++) were written by J. Michael Word and updated by Andrew Leaver-Fay and other collaborators in Jack Snoeyink's group. The latest versions of all the software, compiled for multiple platforms, plus source and documentation files are available free from the Software section of the kinemage web site (http://kinemage.biochem.duke.edu). The *KiNG* documentation is included in its software download package, and is also available there separately as file king-manual.pdf.

Kinemage development is supported by NIH grants GM073919 and GM 73930, and historically by the Protein Society and by GM15000.

Chapter 21.6. *MolProbity*: all-atom structure validation for macromolecular crystallography

V. B. Chen, W. B. Arendall III, J. J. Headd, D. A. Keedy, R. M. Immormino, G. J. Kapral, L. W. Murray, J. S. Richardson and D. C. Richardson

21.6.1. Summary of *MolProbity* flow and user interactions

The usual interaction with *MolProbity* (Davis *et al.*, 2007) is through the internet at http://molprobity.biochem.duke.edu or as a main menu item on our general laboratory website at http://kinemage.biochem.duke.edu. [For bulk users, it is also possible to set up your own local *MolProbity* server or to use the individual programs in command-line mode. *MolProbity*-style validation is also now available in *PHENIX* (see Section 21.6.6).] Tutorial exercises for the whole process of diagnosing and fixing errors can be found on the kinemage site under Teaching/MolProbity.

A typical *MolProbity* session starts with the user uploading a coordinate file of their own or fetching one from the PDB or NDB databases (Berman *et al.*, 1992, 2000) in new or old PDB format or in mmCIF format. After checking the thumbnail image and listed characteristics of the input file, and editing or reloading if needed, H atoms are added and optimized, with automated correction of Asn/Gln/His 180° flips if needed (Word, Lovell, Richardson & Richardson, 1999).

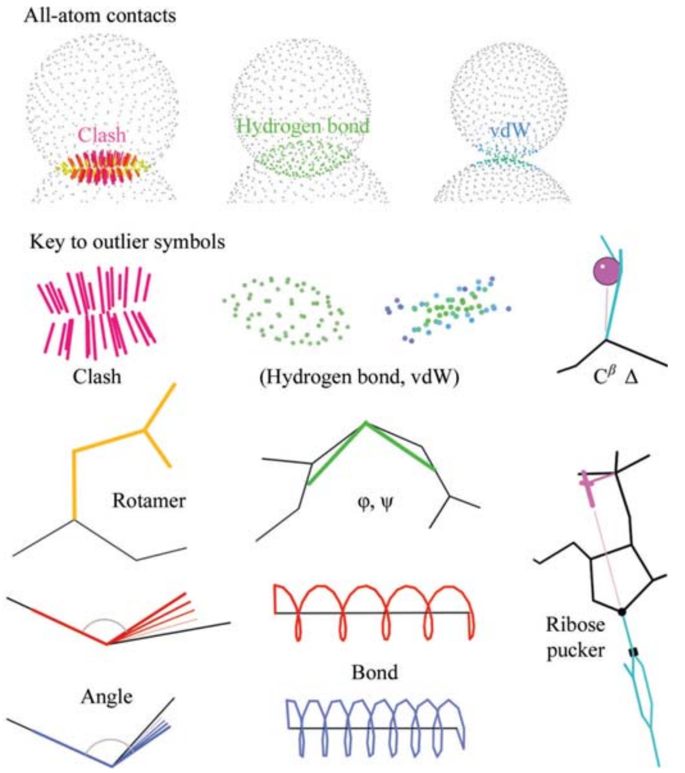

Figure 21.6.1.1
An outlier legend, showing each symbol used in a *MolProbity* multi-criterion kinemage and illustrating the relationship of the three types of all-atom contact to the atomic van der Waals (vdW) surfaces (spheres of small grey dots). The symbols for favourable hydrogen bonds and vdW contacts are included for completeness, as well as the hot-pink spikes of a clash outlier. A C^{β} deviation of ≥ 0.25 Å is shown as a magenta ball centred on the ideal C^{β} position and tangent to the modelled position. Bad rotamers are shown as gold side chains and Ramachandran outliers as heavy green lines to the midpoints of the two peptides. Bond-angle outliers are indicated by a fan of lines from the ideal to the modelled bond (red if wide, blue if narrow). Bond-length outliers are indicated as stretched (red) or compressed (blue) springs. A suspicious ribose pucker is diagnosed by the perpendicular distance from the 3′ (following) phosphate to the line of the glycosidic C1′—N1/9 bond and is flagged by a representation of that construction (in magenta if too short, as here, and in purple if too long).

The user then chooses which validation analyses to run and what reports and output files to generate. The *MolProbity* interface adjusts the defaults and options presented and even the page flow depending on user choices and on the properties of the file being worked on. These adjustments make *MolProbity* simple for novice users, while at the same time allowing advanced users to have great control over their runs. The core 'glue' that generates the HMTL code controlling the main user interface and programmatic interactions of *MolProbity* is implemented in the PHP programming language. Underlying the PHP core, the majority of the analysis tasks in *MolProbity* are performed by individual programs written in a range of languages, including C, C++, Java and Perl. It uses *REDUCE* and *PROBE* for all-atom contact analysis, *RAMALYZE*, *ROTALYZE*, *DANGLE*, *SILK* and *SUITENAME* for other criteria and *KiNG* (see Chapter 21.5) for three-dimensional visualization of the structure and its validation markers directly in the browser. Fig. 21.6.1.1 shows a key to *MolProbity*'s graphical markers for validation outliers. Further details are provided below on the specific analyses that *MolProbity* can perform. The validation results are reported in the form of summaries, charts, two-dimensional and three-dimensional graphics and output files for download.

The crucial final step in the *MolProbity* process is for the crystallographer to download the result files and work off-line to correct as many of the diagnosed problems as feasible. Rebuilding with consideration of the validation outliers, the electron density and the surrounding model is usually performed either in *Coot* (Emsley *et al.*, 2010) or in *KiNG* (Chen *et al.*, 2009; Chapter 21.5). At resolutions of about 2.5 Å or better it is possible to correct the great majority of outliers (Arendall *et al.*, 2005), with an order-of-magnitude improvement in the various *MolProbity* scores and some improvement in geometry, map quality, R factor and $R_{\rm free}$. An example is shown in Fig. 21.6.1.2 with before-and-after multi-criterion kinemages.

21.6.2. Validation analyses

21.6.2.1. *Addition of H atoms*

The presence of H atoms (both nonpolar and polar) is a critical prerequisite for all-atom contact analysis. Although refinement using H atoms is becoming more common, most crystal structures are still deposited without H atoms. Once a coordinate file has been uploaded, *MolProbity* detects whether the file contains a suitable number of H atoms; if not, then the 'Add H atoms' option is presented to users first. *MolProbity* uses the software *REDUCE* (Word, Lovell, Richardson & Richardson, 1999; Davis *et al.*, 2007) to add and optimize hydrogen positions in both protein and nucleic acid structures, including ligands, but does not add explicit H atoms to waters. OH, SH and NH_3 groups (but

Copyright © 2012 International Union of Crystallography

not methyl groups) are rotationally optimized and His protonation is chosen within each local hydrogen-bond network, including interactions with the first shell of explicit waters.

A common problem is that the side-chain ends of Asn, Gln and His are easily fitted 180° backwards, since the electron density alone cannot usually distinguish the correct choice of orientation. *REDUCE* can automatically diagnose and correct these types of systematic errors by considering all-atom steric overlaps as well as hydrogen bonding within each local network. Automatic correction of Asn/Gln/His flips is the default option in *MolProbity* during addition of H atoms. *MolProbity* presents each potential flip correction to the user in kinemage view so they have the option of inspecting the before-and-after effects of each flip and approving (or rejecting) each correction. Fig. 21.6.2.1 shows an example of a simple Gln flip that is unquestionably correct but that could not have been decided on the basis of hydrogen bonding alone. Other examples can be much more complex, with rotatable OH positions, large hydrogen-bond networks and multiple competing interactions evaluated exhaustively.

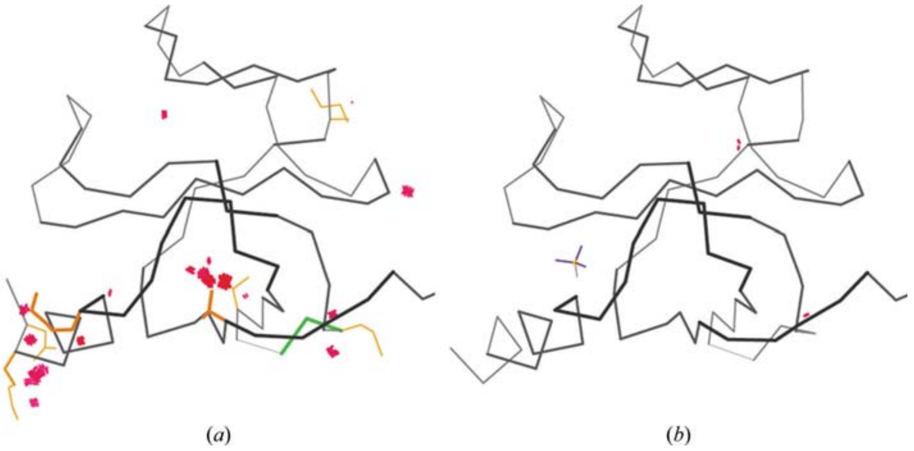

Figure 21.6.1.2
Two multi-criterion validation kinemages illustrating the successful outcome of an overall process of *MolProbity* diagnosis and structure improvement. (*a*) The original 1lpl Cap-Gly structure (Li *et al.*, 2002) shows three major clusters of clash, rotamer and Ramachandran problems plus a few isolated outliers. (*b*) The corrected 1tov structure (Arendall *et al.*, 2005) has essentially no outliers, a 4% lower $R_{\rm free}$, a bound sulfate and an additional turn of helix at the N-terminus.

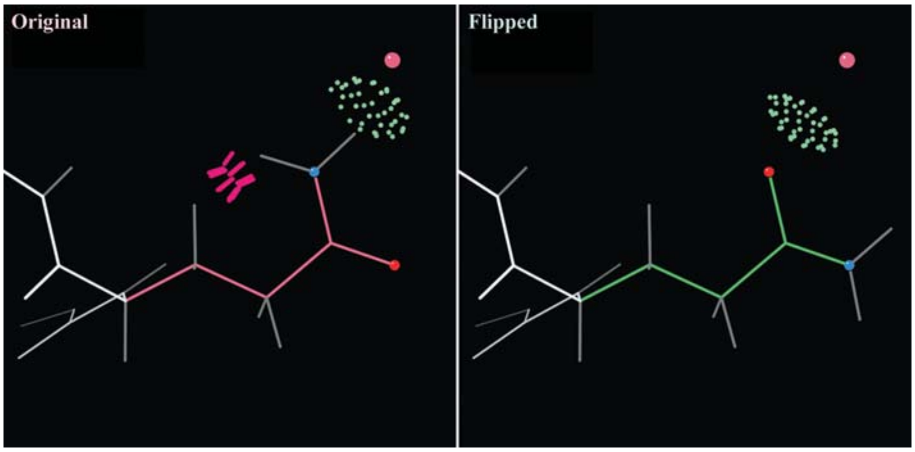

Figure 21.6.2.1
The simple 'flip' correction of a Gln side-chain amide in the 2dq4 threonine 3-dehydrogenase structure (R. Omi, T. Yao, M. Goto, I. Miyahara & K. Hirotsu, unpublished work), a better-than-average 2.5 Å resolution structure. Both orientations make a hydrogen bond to the crystallographic water, but the original has a serious internal clash of the NH_2 group with its own C^{β} hydrogen.

Users can also choose to add H atoms without Asn/Gln/His flips, which is useful in evaluating the atomic coordinates as they were deposited, but which rejects the easiest and most robustly correct improvement that can be made in a crystallographic model (Word, Lovell, Richardson & Richardson, 1999; Higman *et al.*, 2004). If flips are performed, the user needs to download and use the corrected PDB file (either with or without the H atoms) in order to benefit.

21.6.2.2. All-atom contact analysis

Once H atoms have been added to (or detected in) a structure, then the complete 'Analyze all-atom contacts and geometry' option is enabled. A main feature of this option is the all-atom contact analysis, which is performed by the program *PROBE* (Word, Lovell, LaBean *et al.*, 1999). *PROBE* operates by, in effect, rolling a 0.5 Å diameter ball around the van der Waals surfaces of atoms to measure the amount of overlap between pairs of nonbonded atoms. When non-donor–acceptor atoms overlap by more than 0.4 Å, *PROBE* denotes the contact as a serious clash, which is included in the reported clashscore and is shown in kinemage format as a cluster of hot-pink spikes in the overlap region (Fig. 21.6.1.1). Such large overlaps cannot occur in the actual molecule, but mean that at least one of the two atoms is modelled incorrectly. *MolProbity* allows users to select any combination of clashes, hydrogen bonds and van der Waals contacts to calculate and display on the structure. By default, all three are enabled for structures that are not excessively large; for large structures, van der Waals contacts are deselected.

The 'clashscore' is the number of serious clashes per 1000 atoms. It is reported in the *MolProbity* summary (top of Fig. 21.6.2.2), with a red/yellow/green colour coding for absolute quality. The structure's percentile rank for clashscore value within the relevant resolution range is also given. In the detailed sortable 'multi-chart' (an extract is shown below the summary in Fig. 21.6.2.2), the worst clash ≥0.4 Å is listed for each residue and highlighted in pink.

21.6.2.3. Torsion-angle combinations: updated Ramachandran and rotamer analyses

Also included in the 'Analyze all-atom contacts and geometry' option is an evaluation of where residues fall in the multi-dimensional distributions of Ramachandran backbone φ, ψ angles and side-chain rotamer χ angles. The reference distributions are currently from 100 000 residues in 500 files, quality-filtered at both the file and the residue level. The Ramachandran plots are separated for Gly, Pro and pre-Pro residue types; the general plot has only one in 2000 residues outside the 'allowed' contour, which is the same probability as a 3.5σ outlier in a normal distribution. The three specific plots can be robustly contoured only down to excluding one in 500 residues (about 3σ) in the current reference data, but will soon be updated. By ‘robust’ we mean that the contour does not shift with further improvement in resolution or B or with different subselections of the data. When values plateau in this way we can define clear absolute goals for the measure, such as 98% for Ramachandran favoured, <0.2% for Ramachandran outliers, <1% for poor rotamers and 0 for C^{β} deviation outliers; other goal levels given in the summary are more arbitrary.

However, Ramachandran outliers are of course not rare in general; they increase as a function of resolution (Arendall *et al.*, 2005) and especially of B factor (Lovell *et al.*, 2003). Fig. 21.6.2.3(*a*) shows the points for an above-average 2.5 Å resolution structure plotted on the smoothed contours of the reference distribution for favoured (enclosing 98% of the good data) and allowed (enclosing 99.95% of the good data). The four Ramachandran plots are presented in kinemage and pdf form, scores are given in the multi-criterion chart (Fig. 21.6.2.2) and outliers are flagged in green on the multi-criterion kinemage (Figs. 21.6.1.1 and 21.6.1.2).

Multi-dimensional rotamer distributions for the individual side-chain types are currently contoured only down to excluding 1% of the high-quality data. [All such distributions used in *MolProbity* will be periodically updated to take advantage of the expanding reference data.] These are updates of the ‘penultimate rotamer library’

Figure 21.6.2.3

The general case Ramachandran kinemage and the C^{β} deviation kinemage for file 2dq4. In (*a*) the φ, ψ values for each residue are plotted on a background of the smoothed contours from high-quality data (see text). Over 98% lie inside the inner ‘favoured’ 98% contour, but there are seven outliers outside the outer 99.95% contour. Gly, Pro and pre-Pro residues are on separate plots (not shown). In (*b*) the C^{β} deviation kinemage shows each residue's C^{β} position relative to an ideal C^{β} and its three bond vectors (grey lines). Circles mark the deviation distances, with the yellow circle at the 0.25 Å cutoff for outliers. Most of the distribution is good, but an adjacent Leu and Trp in each chain (labelled) are part of an outlier cluster and probably reflect distortions caused by a local fitting problem.

(Lovell *et al.*, 2000), although certainly not yet ultimate. Above the 1% level, sets of χ values are assigned to named rotamers; below 1% they are designated as poor rotamers, not outliers, since they are disfavoured but quite possible if stabilized by tight packing or a couple of good hydrogen bonds. However, there is no justification for fitting poor rotamers on the protein surface with no interactions to hold them in an unfavourable conformation. Some bad rotamers result from systematic errors arising from fitting branched side chains (Thr/Val/Ile/Leu/Arg) backwards into ambiguous density. The two major systematic errors for Leu are described in Lovell *et al.* (2000) and are given zero rotamer-quality scores in *MolProbity*; other cases are discussed in Section 21.6.3.2. Poor rotamers are scored in the multi-criterion chart and are represented by gold side chains in the multi-criterion kinemages (Figs. 21.6.1.1 and 21.6.1.2). The *MolProbity* summary (top of Fig. 21.6.2.2) reports the percentage of residues with poor rotamers, Ramachandran outliers and Ramachandran favoured conformations.

21.6.2.4. Covalent-geometry analyses

MolProbity now evaluates backbone bond-length and bond-angle outliers. Mean overall deviations in geometrical parameters are a measure of correct procedures and weights in refinement, but not of structural accuracy. Local geometry outliers $\geq 4\sigma$, however, are most often the indirect result of local misfitting and are thus very useful diagnostics, especially for bond angles. [Note that some such problems occur even at very high resolution, either at the ends of alternate conformations or in under-restrained regions with high *B* factor.] A major recent addition to *MolProbity* is the ability to assess the ideality of covalent backbone geometry for protein and RNA with the Java program *DANGLE*, which is also available for standalone command-line use from the software section at http://kinemage.biochem.duke.edu. New and more intuitive visualizations for backbone bond-length and angle deviations have been developed for display on the three-dimensional structure. For bond lengths, a 'spring' is drawn along the bond axis and scaled such that the ideal distance is equivalent to six turns and 4σ deviation corresponds to one turn of stretching or compaction (Fig. 21.6.1.1). For bond angles, bold lines are drawn to represent the ideal angle and a fan of increasingly thin lines fades out across the model *versus* ideal angle difference to highlight the extent of the deviation (Fig. 21.6.1.1). In each case model values greater (or less) than the corresponding ideal value by at least 4σ are displayed in red (or blue) and are listed on the multi-criterion chart. Protein backbone parameters were derived from Engh & Huber (Chapter 18.3) and nucleic acid backbone parameters from Parkinson *et al.* (1996).

The C^{α} atom is where local problems with backbone or side-chain fitting must be reconciled. This affects the bond angles or improper dihedrals that define the C^{β} position, but can be manifested in almost any combination of those individual parameters. Therefore, *MolProbity* evaluates the resulting overall distortion of the C^{β} position from ideality, called the C^{β} deviation (Lovell *et al.*, 2003). Residues with a C^{β} deviation of ≥ 0.25 Å are flagged in the chart and shown in the kinemage as a magenta ball centred on the ideal position (calculated from the backbone coordinates and allowing for changes in the τ angle) and tangent to the modelled position (Fig. 21.6.1.1), since we have found that values of ≥ 0.25 Å are very often correlated with some form of local misfitting. Fig. 21.6.2.3(*b*) shows a separate plot produced for all the C^{β} deviation values in a structure, shown relative to the ideal C^{β} position. The Leu and Trp C^{β} outliers in each chain form a tight turn with a suspicious peptide orientation and eight other outliers and so must represent some form of misfitting.

21.6.2.5. Nucleic acid analyses

Nucleic acids are treatable equivalently to proteins for all-atom contacts and clashscore and for bond-length and bond-angle analyses, as long as the correct parameter sets are used. Both DNA and RNA show more non-uniform distribution of local problems than do proteins, with the bases and phosphates located well and the rest of the sugar-phosphate backbone very prone to errors (Word, Lovell, Richardson & Richardson, 1999; Murray *et al.*, 2003), since it has many torsion variables and rather indistinct electron density at moderate resolutions. All-atom contacts are very helpful in diagnosing backbone misfitting, especially for RNA structures, which are rapidly gaining biological interest and structural attention.

In addition, *MolProbity* now includes diagnosis of suspect ribose puckers and torsion-angle analysis of preferred RNA backbone conformers. We have found that the dominant C3′-*endo* and C2′-*endo* sugar puckers are highly correlated to the perpendicular distance between the C1′–N1/9 glycosidic bond vector and the following (3′) phosphate: >2.9 Å for C3′-*endo* and <2.9 Å for C2′-*endo*. *MolProbity* checks this distance against the modelled sugar pucker, as well as outliers in individual ε or δ values. All such outliers are listed in the multi-chart and ribose-pucker outliers are flagged in the kinemage (Fig. 21.6.1.1). An example is shown in Fig. 21.6.2.4, where what should have been a C2′-*endo* pucker (by the short perpendicular) was fitted as an intermediate unfavourable pucker close to the more common default C3′-*endo* pucker, also producing geometry and ε outliers.

High-dimensional analysis of the combinations of backbone torsion angles within an RNA 'suite' (the unit from sugar to sugar) has shown that there are distinct 'rotameric' backbone conformers. The RNA Ontology Consortium has defined a two-character nomenclature and an initial set of 54 favourable RNA backbone conformers (Richardson *et al.*, 2008). We created the *SUITENAME* program to identify either the named conformer or an outlier for each suite in an RNA structure. These conformers and their 'suiteness' quality score are listed in the *MolProbity* multi-chart.

21.6.2.6. The overall MolProbity score

In response to user demand, the '*MolProbity* score' provides a single number that represents the central *MolProbity* protein quality statistics. It is a log-weighted combination of the clashscore, percentage Ramachandran not favoured and percentage bad side-chain rotamers, giving one number that reflects the crystallographic resolution at which those values would be expected. Therefore, a structure with a numerically lower *MolProbity* score than its actual crystallographic resolution is, quality-wise, better than the average structure at that resolution. There is some distortion in the fit at very high or very low resolutions; for these ranges it is preferable to judge by the resolution-specific percentile score, which is also reported in the summary. Percentile scores are currently given for clashscore and for *MolProbity* score relative to the cohort of PDB structures within 0.25 Å of the file's resolution.

Figure 21.6.2.4
Close-up of a ribose-pucker outlier in the multi-criterion kinemage for 1n78, with backbone and bases turned on. C574 has a short phosphate-to-glycosidic bond perpendicular (magenta line and cross), but was fitted with an intermediate pucker near C3′-*endo*. The bad pucker torques the connected groups strongly, probably causing the bond-angle outliers (red) and steric clashes (hot-pink spikes). Note that C574 is in the binding interface between RNA (white backbone) and enzyme (yellow backbone) close to the active site.

21.6.3. Correction of outliers

21.6.3.1. *Manual rebuilding*

Except for Asn/Gln/His flip corrections, *MolProbity* does not yet directly include the ability to correct the errors it finds in structures; it relies on users having access to standalone local software for rebuilding and refinement. The standalone version of *KiNG* has some rebuilding tools for modelling side chains and making small local 'backrub' adjustments to structures, with the help of electron-density display, interactive contact dots and rotamer evaluation (Davis *et al.*, 2006; Chen *et al.*, 2009; Chapter 21.5). Fig. 21.6.3.1 illustrates such a correction process in *KiNG*, rebuilding a backward-fitted leucine with a clash and a bad rotamer (one of the cases of a systematic error), resulting in an ideal geometry side chain with an excellent rotamer and well packed all-atom contacts. The top view shows that the original and rebuilt side chains fit the terminal methyls into the same rather ambiguous density, but move the C$^{\gamma}$ substantially. More recent versions of this DNA polymerase structure (*e.g.* PDB code 2hhv at 1.55 Å resolution; Warren *et al.*, 2006) all use the new conformation. Manual rebuilding is facilitated by the fact that all-atom clashes are inherently directional, as are bond-angle distortions, while a good library of rotamer choices helps the user test all the alternatives.

For more extensive refitting, a fully featured crystallographic rebuilding program such as *Coot* (Emsley *et al.*, 2010) is needed. *MolProbity* generates 'to-do' scripts that can be read into *Coot*, bringing up a button list, where each entry will zoom to a problem area. In combination with the ability of *Coot* to use *REDUCE* and *PROBE* interactively to generate all-atom contact dots, these features make it easier to address the problems diagnosed by *MolProbity*. Any rebuilding that moves atoms must of course then undergo further crystallographic refinement. Our own laboratory tested the combined cycle of *MolProbity*, rebuilding and refinement on about 30 protein structures as part of the SouthEast Collaboratory for Structural Genomics (Arendall *et al.*, 2005), finding that its early application led to a smoother structure-solution process and demonstrably better final structures. In addition to backward-fitted side chains, commonly corrected problems included peptide flips, switched backbone and side chain near chain ends, 'waters' that were really ions, noise peaks or unfit alternate conformations and occasionally a shift in sequence register. Many other crystallographic groups have since adopted these methods.

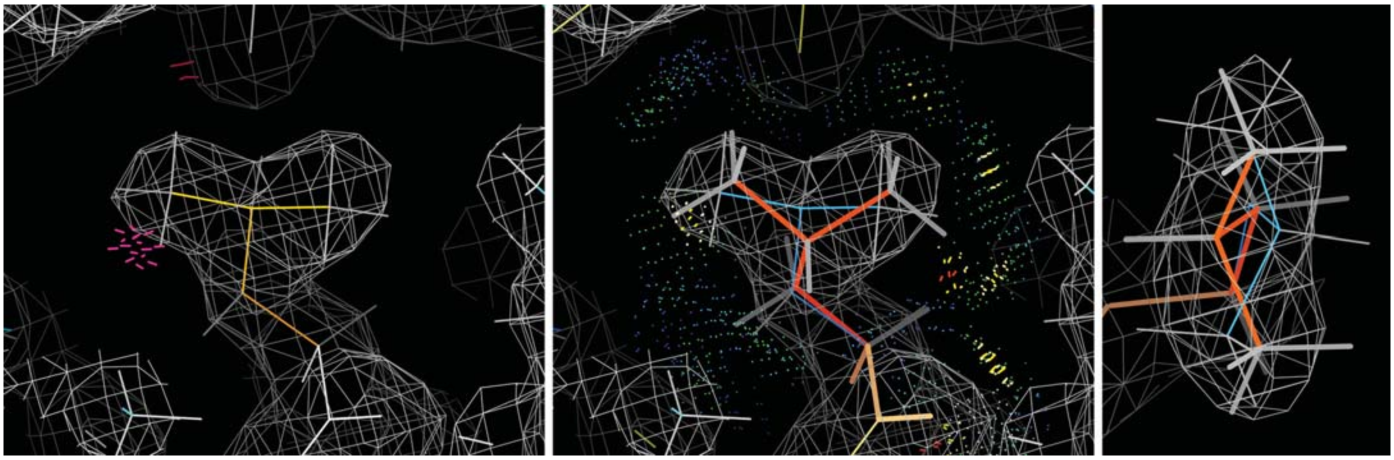

Figure 21.6.3.1
Rebuilding of a backward-fitted Leu side chain in *KiNG* off-line in the DNA polymerase 1xwl at 1.7 Å resolution (Kiefer *et al.*, 1997). The original (left) fits the density fairly well but is a rotamer outlier with a clash. One of the two best Leu rotamers also fits the density well with good all-atom packing. The top view (right) shows the 180° relationship of the two conformations.

21.6.3.2. Automated corrections

For correcting RNA-suite outliers, we have collaboratively developed the independent program *RNABC* (Wang *et al.*, 2008), which performs an automated search for more suitable backbone conformations of an RNA suite diagnosed with a bad ribose pucker or serious clashes. It leaves the more accurately determined bases and P atoms fixed in place and performs a pruned but systematic search through the other parameters, outputting all acceptable alternatives found within user-set tolerance limits.

Recently, we have developed and tested the *AUTOFIX* program for automated correction of diagnosed backward-fitted Thr, Val, Leu and Arg side chains (Headd *et al.*, 2009). In contrast to Asn/Gln/His flips, which simply exchange atoms and do not change the agreement with the data, these more complex side chains require real-space refinement in order to determine the proper correction and crystallographic re-refinement after the approximate 180° flips have been made. The original version used *Coot* to perform rotamer selection and real-space refinement for the proposed corrections, with *MolProbity* diagnosis before and after. Results were checked by re-refinement. Run on a sample of 945 PDB files, *AUTOFIX* accepted corrections for over 40% of diagnosed bad Thr, Val and Leu side chains and 15% of bad Arg side chains, or 3679 corrected side chains. The most important of our requirements for *AUTOFIX* is that it does no harm; we are willing to miss some of the possible corrections in order to ensure that those we accept are essentially always true improvements. Thr and Arg, in particular, make hydrogen bonds that are often important at active sites or binding interfaces and since they are asymmetrical these interactions change drastically if the side chain is fitted backwards. Such improvements were often seen in the test set. A successor to *AUTOFIX* has been built into *phenix.refine*, called by setting fix_rotamers = True.

21.6.4. Other *MolProbity* utility functions

21.6.4.1. Interface analysis

PROBE can also be used to calculate the all-atom contacts at interfaces, *e.g.* between two chains of a structure or between a protein and a ligand. Access to this feature is provided in *MolProbity* by the 'Visualize interface contacts' analysis option after H atoms have been added. The user is required to choose the chains and/or the molecular types for which to calculate the contacts (*e.g.* protein *versus* protein or protein *versus* heteroatoms or RNA). This functionality creates both a kinemage with the resulting all-atom contacts displayed on the model and a text list of the atom pairs in contact.

21.6.4.2. Protein loop fitting

MolProbity includes the Java software *JIFFILOOP* (Chen, 2010) for providing potential protein-fragment conformations that can fit within a gap in a protein structure. We have defined a seven-parameter system that describes the spatial relationship between any two peptides. Briefly, this system consists of the sequence separation, the distance between the two inner C$^{\alpha}$ atoms, two pseudo-angles and three pseudo-dihedrals. We used this system to create a library of *B*-factor-filtered fragments from one to 15 peptides long from our Top5200 database of structures, a set of structures chosen from each 70% nonredundant group defined by the PDB, requiring resolution < 2.0 while optimizing *MolProbity* score. *MolProbity* runs *JIFFILOOP* to search this library for candidate fragments to fill gaps within a structure. Alternatively, users can enter beginning and ending residue numbers and *MolProbity* will search for fragments which can fit between those two residues. Because this process can be fairly time-intensive, *JIFFILOOP* is not listed under 'Suggested Tools' and is currently only accessible under 'All Tools' or at the Site map. Also, owing to the size of this package, it must be added separately to the installation for a standalone *MolProbity* server.

21.6.4.3. Kinemage construction and viewing

MolProbity provides scripts (under the 'Make simple kinemages' option) for constructing a number of commonly used kinemage three-dimensional interactive visualization options such as ribbons and various types of stick figures. This functionality is useful for quick browsing of a structure or for initial creation of an illustration or presentation. The file-input page can also accept upload of pre-existing kinemage files for direct on-line viewing within the built-in kinemage viewer *KiNG*.

21.6.4.4. Other file types and functions

MolProbity uses a built-in PDB 'het_dictionary' for the information needed to add H atoms to small-molecule ligands. The user can construct and read in a custom dictionary if their file contains novel ligands. There is also provision for either uploading or fetching an electron-density map from the Electron Density Server (Kleywegt *et al.*, 2004) in any of several formats to view on-line in *KiNG* together with the model and validation results. To investigate functional sites that span across asymmetric units, one can fetch a biological unit file from the PDB. In the file-editing feature, the user can specify whether multiple 'models' are alternatives (as in an NMR ensemble) or have been pressed into service for the extra chains in the biological unit. Some X-ray structures are now treated as ensembles. For such cases, *MolProbity* internally splits the models and analyses them separately, but constructs an outlier summary strip-chart and a multi-model multi-criterion validation kinemage with both the models and their features under on/off button control. File editing also allows the deletion of chains either before or after hydrogen placement, specifying the resolution of the structure if not given in the file header or removing unwanted H atoms. These tools make it easier and faster to analyse particular parts of a structure using *MolProbity* and they help to maintain compatibility with other older software. These options are always available as separate utility functions, independent of validation or hydrogen content.

21.6.4.5. PDB-format interconversion

The release of the remediated PDB version 3.0 format in August 2007 included a number of significant changes, particularly to H-atom names and to nucleic acid residue and atom names. In order to maintain compatibility with the PDB, we converted the entire *MolProbity* core to use the new format by default. This included updating *REDUCE*, *PROBE*, *KiNG* and *PREKIN*. However, we realized that users might need to analyse files that were still in the older PDB version 2.3 format. In order to maintain backwards compatibility, we created a Remediator script (available as a standalone Perl or Python script) that can interconvert between the old and the new PDB formats. Whenever a file is input, *MolProbity* will scan for the presence of old-format atom names and, if it detects any, then it will run the Remediator script to automatically convert the input file to the new format. After analysis there is then an option available to run the Remediator script and downgrade the output file back into the old version 2.3 format if needed. This allows use of the

MolProbity analysis tools even together with older software that has not been updated to use the new format.

21.6.5. Discussion

21.6.5.1. Global versus local, absolute versus comparative

There are three quite different purposes served by structure validation: a gatekeeper function on quality for reviewers or organizations, an aid to crystallographers for obtaining the most model accuracy from their data, and a guide to end users for choosing appropriate structures and confidence levels for the conclusions they want to draw.

Validation criteria also come in distinct flavours. Those based on the diffraction data are inherently global with respect to the model; for instance, resolution (which is still the most valuable single-factor estimate of model accuracy) and $R_{\rm free}$ (Brünger, 1992). On the data side, there are also gatekeeper checks for unusual problems such as twinning or gross data incompleteness. R.m.s.d. or r.m.s.*Z*. of deviations from geometrical target values are global, but they only evaluate procedural aspects of refinement and have little to do with model accuracy. Most other validation criteria are inherently local (at the residue or even atom level), including *B* factor, real-space measures such as RSR-*Z* (Kleywegt *et al.*, 2004) and model-only measures such as the various *MolProbity* criteria described here. Any local measure becomes global when expressed in some normalized form across the entire structure, such as an average, a distribution match or a percentage occurrence of outliers.

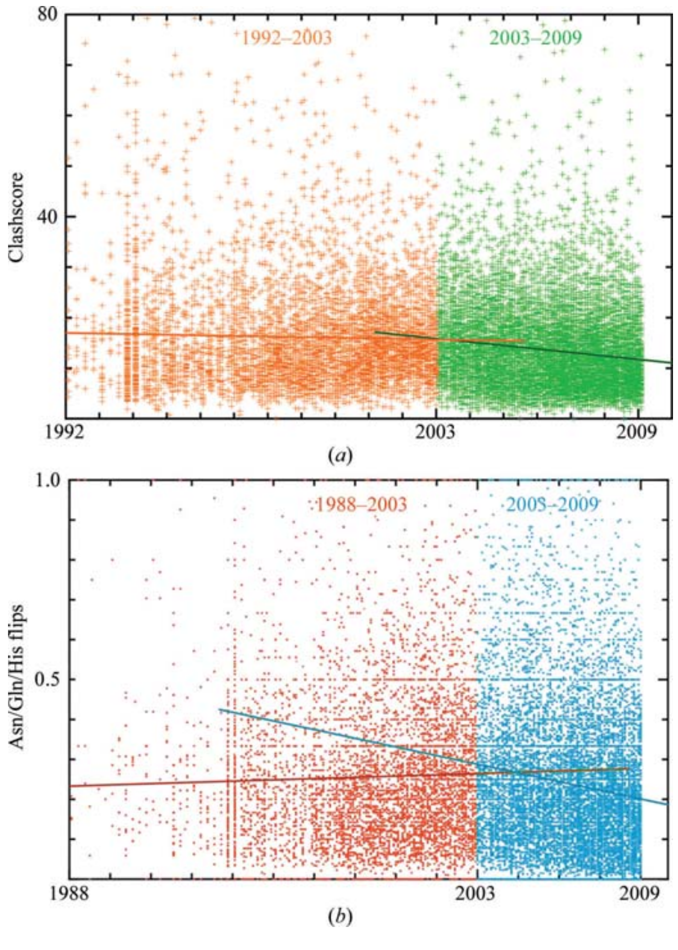

Figure 21.6.5.1
MolProbity-relevant quality criteria as a function of time for all structures in the PDB at a middle range of resolution, separately fitted before and after introduction of the web site. (*a*) All-atom clashscore (see Section 21.6.2.2); (*b*) percentage of Asn/Gln/His flips (see Section 21.6.2.1).

Strictly local measures are usually not resolution-dependent, but their globally defined versions often are. For some purposes, the desirable form of measure is a comparison (usually a percentile rank) with the cohort of PDB structures at similar resolution. *MolProbity* currently provides resolution-group percentiles for clashscore and for *MolProbity* score and will probably expand that to other criteria.

Reviewers/gatekeepers are primarily interested in global relative measures such as resolution-dependent percentiles and to some extent in absolute local flags for judging the support behind specific claims. Crystallographers need global relative measures to judge how well they have made use of their data, but it is the local measures, especially specific outliers, that are crucial to helping them to achieve a more accurate structure and to avoid making any dubious claims in poor local regions (such as an invisible inhibitor). End users need absolute global measures to choose between structures and absolute local measures to judge the reliability of the particular features they find of interest.

Because of the importance of improving and evaluating the accuracy of individual details of biological importance, both in each structure and in the database as a whole, we have chosen in *MolProbity* to emphasize calculation and user-friendly display of local indicators. We have also tried to minimize ‘false alarms’, so that a flagged outlier is almost always worth a close look.

21.6.5.2. Impact on database quality

Since *MolProbity* was first made available in late 2002, serious user work sessions (performing some operation on an input coordinate file) have multiplied by a large factor each year, with a cumulative total that is now approaching 100 000 by thousands of distinct users. In addition, many companies and structural genomics centres run their own *MolProbity* servers internally and some aspects have been incorporated into other software or meta-servers. 80% of *MolProbity* input files are uploaded, presumably by working structural biologists, and the rest are fetched from databases, presumably by end users. Those end users also include students, since *MolProbity* is increasingly being used for instructional exercises in biochemistry classes from high school to graduate level.

MolProbity’s unique feature is clash analysis from all-atom contacts, which provides sensitive new evaluation independent of refinement targets. Not surprisingly, the average clashscore remained constant (either globally or by resolution) up to 2002, since there was then no feasible way of targeting or even measuring all-atom clashes. The percentage of incorrect Asn/Gln/His flips also remained level or rose slightly prior to 2003, despite the availability of a hydrogen-bond-based system in *WHAT IF* (Hooft *et al.*, 1996), and even while refinement methods, automation and Ramachandran and rotamer quality all improved.

To evaluate the contribution *MolProbity* has made to crystallographic model quality in general, we have therefore plotted clashscore and Asn/Gln/His flips as a function of time in Fig. 21.6.5.1, with separate linear fits before and after the end of 2002. Gratifyingly, in both cases there is a clear trend of improvement since 2003. Median values also improve very steadily over that period. Anecdotal evidence indicates that this trend is mainly a consequence of thorough adoption of *MolProbity*-based methods by a small but growing fraction of crystallographers and there is therefore still much scope for further improvement in the future.

21.6.6. *MolProbity* availability

MolProbity is freely available for download from http://molprobity.biochem.duke.edu for use as a local server. This option requires either Linux or MacOSX, together with PHP and Apache. Instructions for installing *MolProbity* locally are included with the download. Having a local installation allows users to access the *MolProbity* analysis tools without internet access, as well as allowing companies with privacy or confidentiality concerns to use *MolProbity*. However, one of the most significant advantages to having a local installation of *MolProbity* is access to command-line tools. These tools provide access to the major analysis tools in *MolProbity* without having to use the web interface. Also, several scripts are included which allow users to run *MolProbity* analysis on a set of files rather than just one at a time. Some of the more useful command-line scripts include the following: scripts for adding H atoms, with or without flips, a script for obtaining overall scores for a set of files and a script for calculating a residue-by-residue analysis of a structure.

For users of the *PHENIX* crystallography system (Adams *et al.*, 2010), nearly all of the main *MolProbity* quality-analysis tools have been incorporated directly into *PHENIX* and are accessible through command-line tools or in the *PHENIX* GUI, including *REDUCE*, *PROBE*, *RAMALYZE*, *ROTALYZE*, *CBETADEV*, *RNA_VALIDATE* and *CLASHSCORE*. Both tabular and graphical results are provided, including three-dimensional display in *KiNG* and links to individual outliers in *Coot*.

All of the individual programs called by *MolProbity* are also available, multi-platform and open source, from the software section at http://kinemage.biochem.duke.edu.

Ian Davis is the initial developer of the *MolProbity* site, Xueyi Wang and Jack Snoeyink programmed *RNABC*, Jeremy Block developed *MolProbity* functions for NMR and the *PHENIX* development team at LBL were very helpful with *AUTOFIX* and with integration of *MolProbity* functions. *MolProbity* development is supported by NIH grant GM73919.

This chapter is based a recent article published in *Acta Crystallographica Section D* (Chen *et al.*, 2010).

PART 22. MOLECULAR GEOMETRY AND FEATURES

Chapter 22.1. Protein geometry: volumes, areas and distances

M. Gerstein and F. M. Richards

22.1.1. Introduction

For geometric analysis, a protein consists of a set of points in three dimensions. This information corresponds to the actual data provided by the experiment, which are fundamentally of a geometric rather than chemical nature. That is, crystallography primarily tells one about the positions of atoms and perhaps an approximate atomic number, but not their charge or number of hydrogen bonds.

For the purposes of geometric calculation, each point has an assigned identification number and a position defined by three coordinates in a right-handed Cartesian system. (These coordinates will be based on the electron density for X-ray derived structures and on nuclear positions for those derived from neutron scattering. Each coordinate is usually assumed to have an accuracy between 0.5 and 1.0 Å.) Normally, only one additional characteristic is associated with each point: its size, usually measured by a van der Waals (VDW) radius. Furthermore, characteristics such as chemical nature and covalent connectivity, if needed, can be obtained from lookup tables keyed on the ID number.

Our model of a protein, thus, is the van der Waals envelope – the set of interlocking spheres drawn around each atomic centre. In brief, the geometric quantities of the model of particular concern in this section are its total surface area, total volume, the division of these totals among the amino-acid residues and individual atoms, and the description of the empty space (cavities) outside the van der Waals envelope. These values are then used in the analysis of protein structure and properties.

All the geometric properties of a protein (*e.g.* surfaces, volumes, distances *etc.*) are obviously interrelated. So the definition of one quantity, *e.g.* area, obviously impacts on how another, *e.g.* volume, can be consistently defined. Here, we will endeavour to present definitions for measuring protein volume, showing how they are related to various definitions of linear distance (VDW parameters) and surface. Further information related to macromolecular geometry, focusing on volumes, is available from http://www.molmovdb.org/geometry/.

22.1.2. Definitions of protein volume

22.1.2.1. Volume in terms of Voronoi polyhedra: overview

Protein volume can be defined in a straightforward sense through a particular geometric construction called the Voronoi polyhedron. In essence, this construction provides a useful way of partitioning space amongst a collection of atoms. Each atom is surrounded by a single convex polyhedron and allocated the space within it (Fig. 22.1.2.1). The faces of Voronoi polyhedra are formed by constructing dividing planes perpendicular to vectors connecting atoms, and the edges of the polyhedra result from the intersection of these planes.

Voronoi polyhedra were originally developed by Voronoi (1908) nearly a century ago. Bernal & Finney (1967) used them to study the structure of liquids in the 1960s. However, despite the general utility of these polyhedra, their application to proteins was limited by a serious methodological difficulty. While the Voronoi construction is based on partitioning space amongst a collection of 'equal' points, all protein atoms are not equal. Some are clearly larger than others. In 1974, a solution was found to this problem (Richards, 1974), and since then Voronoi polyhedra have been applied to proteins.

22.1.2.2. The basic Voronoi construction

22.1.2.2.1. Integrating on a grid

The simplest method for calculating volumes with Voronoi polyhedra is to put all atoms in the system on a fine grid. Then go to each grid point (*i.e.* voxel) and add its infinitesimal volume to the atom centre closest to it. This is prohibitively slow for a real

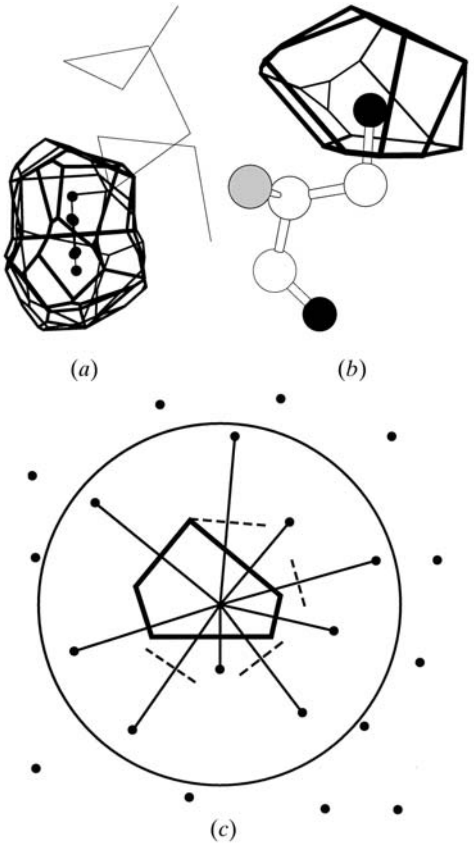

Figure 22.1.2.1
The Voronoi construction in two and three dimensions. Representative Voronoi polyhedra from 1CSE (subtilisin) are shown. (*a*) Six polyhedra around the atoms in a Phe ring. (*b*) A single polyhedron around the side-chain hydroxyl oxygen (OG) of a serine. (*c*) A schematic showing the construction of a Voronoi polyhedron in two dimensions. The broken lines indicate planes that were initially included in the polyhedron but then removed by the 'chopping-down' procedure (see Fig. 22.1.2.4).

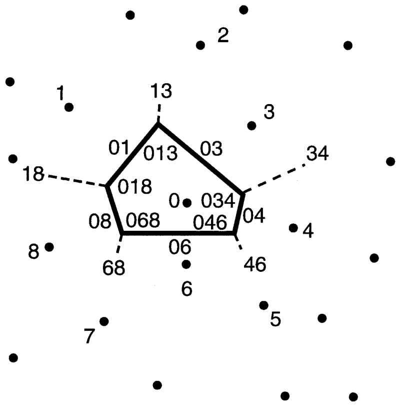

Figure 22.1.2.2
Labelling parts of Voronoi polyhedra. The central atom is atom 0, and each neighbouring atom has a sequential index number (1, 2, 3 . . .). Consequently, in three dimensions, planes are denoted by the indices of the two atoms that form them (*e.g.* 01); lines are denoted by the indices of three atoms (*e.g.* 012); and vertices are denoted by four indices (*e.g.* 0123). In the two-dimensional representation shown here, lines are denoted by two indices, and vertices by three. From a collection of points, a volume can be calculated by a variety of approaches: First of all, the volume of a tetrahedron determined by four points can be calculated by placing one vertex at the origin and evaluating the determinant formed from the remaining three vertices. (The tetrahedron volume is one-sixth of the determinant value.) The determinant can be quickly calculated by a vector triple product, $\mathbf{w} \cdot (\mathbf{u} \times \mathbf{v})$, where $\mathbf{u}$, $\mathbf{v}$ and $\mathbf{w}$ are vectors between the vertex selected to be the origin and the other three vertices of the tetrahedron. Alternatively, the volume of the pyramid from a central atom to a face can be calculated from the usual formula $Ad/3$, where A is the area of the face and d is the distance to the face.

protein structure, but it can be made somewhat faster by randomly sampling grid points. It is, furthermore, a useful approach for high-dimensional integration (Sibbald & Argos, 1990).

More realistic approaches to calculating Voronoi volumes have two parts: (1) for each atom find the vertices of the polyhedron around it and (2) systematically collect these vertices to draw the polyhedron and calculate its volume.

22.1.2.2.2. *Finding polyhedron vertices*

In the basic Voronoi construction (Fig. 22.1.2.1), each atom is surrounded by a unique limiting polyhedron such that all points within an atom's polyhedron are closer to this atom than all other atoms. Consequently, points equidistant from two atoms lie on a dividing plane; those equidistant from three atoms are on a line, and those equidistant from four atoms form a vertex. One can use this last fact to find all the vertices associated with an atom easily. With the coordinates of four atoms, it is straightforward to solve for possible vertex coordinates using the equation of a sphere. [That is, one uses four sets of coordinates (x, y, z) and the equation $(x-a)^2 + (y-b)^2 + (z-c)^2 = r^2$ to solve for the centre (a, b, c) and radius (r) of the sphere.] One then checks whether this putative vertex is closer to these four atoms than any other atom; if so, it is a real vertex.

Note that this procedure can fail for certain pathological arrangements of atoms that would not normally be encountered in a real protein structure. These occur if there is a centre of symmetry, as in a regular cubic lattice or in a perfect hexagonal ring in a protein (see Procacci & Scateni, 1992). Centres of symmetry can be handled (in a limited way) by randomly perturbing the atoms a small amount and breaking the symmetry. Alternatively, the 'chopping-down' method described below is not affected by symmetry centres – an important advantage to this method of calculation.

22.1.2.2.3. *Collecting vertices and calculating volumes*

To collect the vertices associated with an atom systematically, label each one by the indices of the four atoms with which it is associated (Fig. 22.1.2.2). To traverse the vertices on one face of a polyhedron, find all vertices that share two indices and thus have two atoms in common, *e.g.* a central atom (atom 0) and another atom (atom 1). Arbitrarily pick a vertex to start at and walk around the perimeter of the face. One can tell which vertices are connected by edges because they will have a third atom in common (in addition to atom 0 and atom 1). This sequential walking procedure also provides a way of drawing polyhedra on a graphics device. More importantly, with reference to the starting vertex, the face can be divided into triangles, for which it is trivial to calculate areas and volumes (see Fig. 22.1.2.2 for specifics).

22.1.2.3. *Adapting Voronoi polyhedra to proteins*

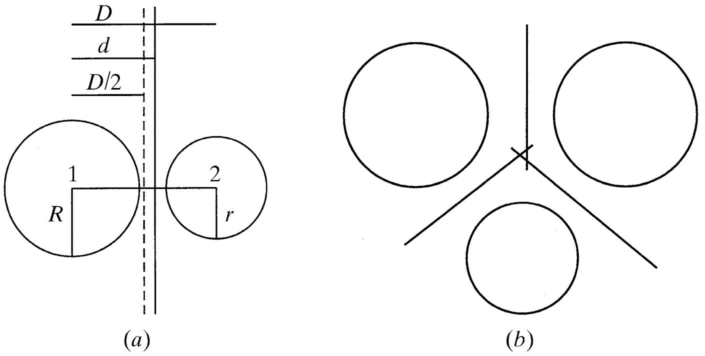
In the procedure outlined above, all atoms are considered equal, and the dividing planes are positioned midway between atoms (Fig. 22.1.2.3). This method of partition, called bisection, is not physically reasonable for proteins, which have atoms of obviously different size (such as oxygen and sulfur). It chemically misallocates volume, giving excess to the smaller atom.

Two principal methods of repositioning the dividing plane have been proposed to make the partition more physically reasonable: method B (Richards, 1974) and the radical-plane method (Gellatly & Finney, 1982). Both methods depend on the radii of the atoms in contact (R for the larger atom and r for the smaller one) and the distance between the atoms (D). As shown in Fig. 22.1.2.3, they position the plane at a distance d from the larger atom. This distance is always set such that the plane is closer to the smaller atom.

22.1.2.3.1. *Method B and a simplification of it: the ratio method*

Method B is the more chemically reasonable of the two and will be emphasized here. For atoms that are covalently bonded, it divides the distance between the atoms proportionaly according to their covalent-bond radii:

$$d = DR/(R + r). \qquad (22.1.2.1)$$



(*a*) (*b*)

Figure 22.1.2.3
Positioning of the dividing plane. (*a*) The dividing plane is positioned at a distance d from the larger atom with respect to radii of the larger atom (R) and the smaller atom (r) and the total separation between the atoms (D). (*b*) Vertex error. One problem with using method B is that the calculation does not account for all space, and tiny tetrahedra of unallocated volume are created near the vertices of each polyhedron. Such an error tetrahedron is shown. The radical-plane method does not suffer from vertex error, but it is not as chemically reasonable as method B.

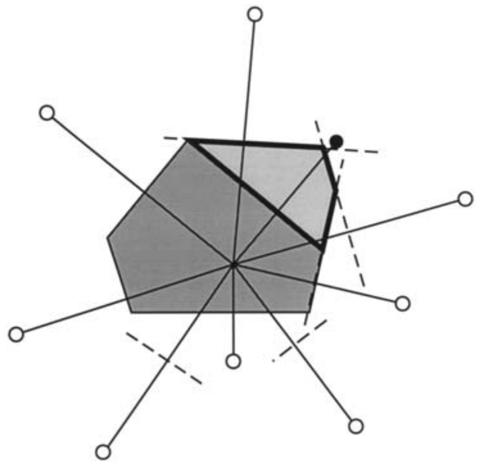


Figure 22.1.2.4
The 'chopping-down' method of polyhedra construction. This is necessary when using method B for plane positioning, since one can no longer solve for the position of vertices. One starts with a large tetrahedron around the central atom and then 'chops it down' by removing vertices that are outside the plane formed by each neighbour. For instance, say vertex 0214 of the current polyhedron is outside the plane formed by neighbour 6. One needs to delete 0214 from the list of vertices and recompute the polyhedron using the new vertices formed from the intersection of the plane formed by neighbour 6 and the current polyhedron. Using the labelling conventions in Fig. 22.1.2.2, one finds that these new vertices are formed by the intersection of three lines (021, 024 and 014) with plane 06. Therefore one adds the new vertices 0216, 0246 and 0146 to the polyhedron. However, there is a snag: it is necessary to check whether any of the three lines are not also outside of the plane. To do this, when a vertex is deleted, all the lines forming it (*e.g.* 021, 024, 014) are pushed onto a secondary list. Then when another vertex is deleted, one checks whether any of its lines have already been deleted. If so, this line is not used to intersect with the new plane. This process is shown schematically in two dimensions. For the purposes of the calculations, it is useful to define a plane created by a vector $\mathbf{v}$ from the central atom to the neighbouring atom using a constant K so that for any point $\mathbf{u}$ on the plane $\mathbf{u}\cdot\mathbf{v} = K$. If $\mathbf{u}\cdot\mathbf{V} > K$, $\mathbf{u}$ is on the wrong side of the plane, otherwise it is on the right side. A vertex point $\mathbf{w}$ satisfies the equations of three planes: $\mathbf{w}\cdot\mathbf{v}_1 = K_1$, $\mathbf{w}\cdot\mathbf{v}_2 = K_2$ and $\mathbf{w}\cdot\mathbf{v}_3 = K_3$. These three equations can be solved to give the components of $\mathbf{w}$. For example, the x component is given by

$$w_x = \begin{pmatrix} K_1 & v_{1y} & v_{1z} \\ K_2 & v_{2y} & v_{2z} \\ K_3 & v_{3y} & v_{3z} \end{pmatrix} \Bigg/ \begin{pmatrix} v_{1x} & v_{1y} & v_{1z} \\ v_{2x} & v_{2y} & v_{2z} \\ v_{3x} & v_{3y} & v_{3z} \end{pmatrix}.$$

For atoms that are not covalently bonded, method B splits the remaining distance between them after subtracting their VDW radii:

$$d = R + (D - R - r)/2. \qquad (22.1.2.2)$$

For separations that are not very different to the sum of the radii, the two formulae for method B give essentially the same result. Consequently, it is worthwhile to try a slight simplification of method B, which we call the 'ratio method'. Instead of using equation (22.1.2.1) for bonded atoms and equation (22.1.2.2) for non-bonded ones, one can just use equation (22.1.2.2) in both cases with either VDW or covalent radii (Tsai *et al.*, 2001). Doing this gives more consistent reference volumes (manifest in terms of smaller standard deviations about the mean).

22.1.2.3.2. Vertex error

If bisection is not used to position the dividing plane, it is much more complicated to find the vertices of the polyhedron, since a vertex is no longer equidistant from four atoms. Moreover, it is also necessary to have a reasonable scheme for 'typing' atoms and assigning them radii.

More subtly, when using the plane positioning determined by method B, the allocation of space is no longer mathematically perfect, since the volume in a tiny tetrahedron near each polyhedron vertex is not allocated to any atom (Fig. 22.1.2.3). This is called vertex error. However, calculations on periodic systems have shown that, in practice, vertex error does not amount to more than 1 part in 500 (Gerstein *et al.*, 1995).

22.1.2.3.3. 'Chopping-down' method of finding vertices

Because of vertex error and the complexities in locating vertices, a different algorithm has to be used for volume calculation with method B. (It can also be used with bisection.) First, surround the central atom (for which a volume is being calculated) by a very large, arbitrarily positioned tetrahedron. This is initially the 'current polyhedron'. Next, sort all neighbouring atoms by distance from the central atom and go through them from nearest to farthest. For each neighbour, position a plane perpendicular to the vector connecting it to the central atom according to the predefined proportion (*i.e.* from the method B formulae or bisection). Since a Voronoi polyhedron is always convex, if any vertices of the current polyhedron are on the other side of this plane to the central atom, they cannot be part of the final polyhedron and should be discarded. After this has been done, the current polyhedron is recomputed using the plane to 'chop it down'. This process is shown schematically in Fig. 22.1.2.4. When it is finished, one has a list of vertices that can be traversed to calculate volumes, as in the basic Voronoi procedure.

22.1.2.3.4. Radical-plane method

The radical-plane method does not suffer from vertex error. In this method, the plane is positioned according to

$$d = (D^2 + R^2 - r^2)/2D. \qquad (22.1.2.3)$$

22.1.2.4. Delaunay triangulation

Voronoi polyhedra are closely related (*i.e.* dual) to another useful geometric construction called the Delaunay triangulation. This consists of lines, perpendicular to Voronoi faces, connecting each pair of atoms that share a face (Fig. 22.1.2.5).

Delaunay triangulation is described here as a derivative of the Voronoi construction. However, it can be constructed directly from the atom coordinates. In two dimensions, one connects with a triangle any triplet of atoms if a circle through them does not enclose any additional atoms. Likewise, in three dimensions one connects four atoms with a tetrahedron if the sphere through them does not contain any further atoms. Notice how this construction is equivalent to the specification for Voronoi polyhedra and, in a sense, is simpler. One can immediately see the relationship between the triangulation and the Voronoi volume by noting that the volume is the distance between neighbours (as determined by the triangulation) weighted by the area of each polyhedral face. In practice, it is often easier in drawing to construct the triangles first and then build the Voronoi polyhedra from them.

Delaunay triangulation is useful in many 'nearest-neighbour' problems in computational geometry, *e.g.* trying to find the neighbour of a query point or finding the largest empty circle in a

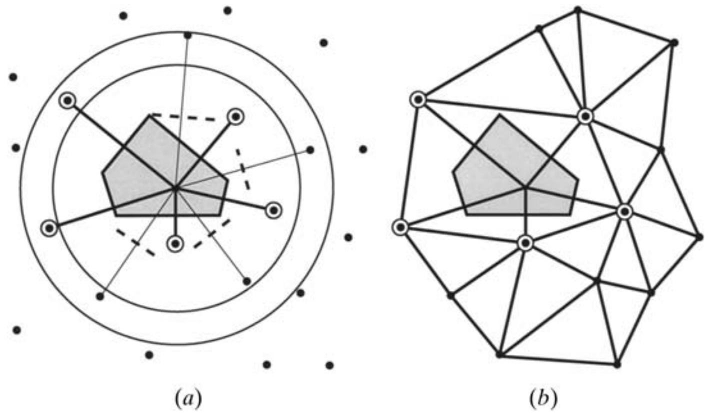

Figure 22.1.2.5
Delaunay triangulation and its relation to the Voronoi construction. (*a*) A standard schematic of the Voronoi construction. The atoms used to define the Voronoi planes around the central atom are circled. Lines connecting these atoms to the central one are part of the Delaunay triangulation, which is shown in (*b*). Note that atoms included in the triangulation cannot be selected strictly on the basis of a simple distance criterion relative to the central atom. The two circles about the central atoms illustrate this. Some atoms within the outer circle but outside the inner circle are included in the triangulation, but others are not. In the context of protein structure, Delaunay triangulation is useful in identifying true 'packing contacts', in contrast to those contacts found purely by distance threshold. The broken lines in (*a*) indicate planes that were initially included in the polyhedron but then removed by the 'chopping-down' procedure (see Fig. 22.1.2.4).

collection of points (O'Rourke, 1994). Since this triangulation has the 'fattest' possible triangles, it is the choice for procedures such as finite-element analysis.

In terms of protein structure, Delaunay triangulation is the natural way to determine packing neighbours, either in protein structure or molecular simulation (Singh *et al.*, 1996; Tsai *et al.*, 1996, 1997). Its advantage is that the definition of a neighbour does not depend on distance. The alpha shape is a further generalization of Delaunay triangulation that has proven useful in identifying ligand-binding sites (Edelsbrunner *et al.*, 1996, 1995; Edelsbrunner & Mucke, 1994; Peters *et al.*, 1996).

22.1.3. Definitions of protein surface

22.1.3.1. The problem of the protein surface

When one is carrying out the Voronoi procedure, if a particular atom does not have enough neighbours the 'polyhedron' formed around it will not be closed, but rather will have an open, concave shape. As it is not often possible to place enough water molecules in an X-ray crystal structure to cover all the surface atoms, these 'open polyhedra' occur frequently on the protein surface (Fig. 22.1.3.1). Furthermore, even when it is possible to define a closed polyhedron on the surface, it will often be distended and too large. This is the problem of the protein surface in relation to the Voronoi construction.

There are a number of practical techniques for dealing with this problem. First, one can use very high resolution protein crystal structures, which have many solvent atoms positioned (Gerstein & Chothia, 1996). Alternatively, one can make up the positions of missing solvent molecules. These can be placed either according to a regular grid-like arrangement or, more realistically, according to the results of molecular simulation (Finney *et al.*, 1980; Gerstein *et al.*, 1995; Richards, 1974).

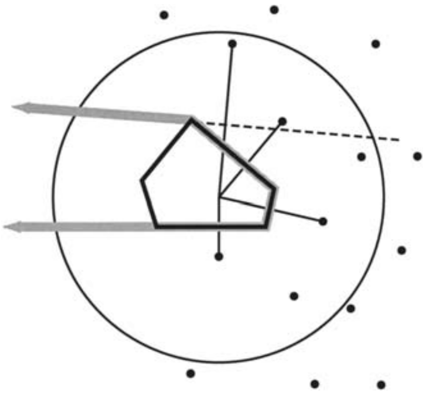

Figure 22.1.3.1
The problem of the protein surface. This figure shows the difficulty in constructing Voronoi polyhedra for atoms on the protein surface. If all the water molecules near the surface are not resolved in a crystal structure, one often does not have enough neighbours to define a closed polyhedron. This figure should be compared with Fig. 22.1.2.1, illustrating the basic Voronoi construction. The two figures are the same except that in this figure, some of the atoms on the left are missing, giving the central atom an open polyhedron. The broken lines indicate planes that were initially included in the polyhedron but then removed by the 'chopping-down' procedure (see Fig. 22.1.2.4).

22.1.3.2. Definitions of surface in terms of Voronoi polyhedra (the convex hull)

More fundamentally, however, the 'problem of the protein surface' indicates how closely linked the definitions of surface and volume are and how the definition of one, in a sense, defines the other. That is, the two-dimensional (2D) surface of an object can be defined as the boundary between two 3D volumes. More specifically, the polyhedral faces defining the Voronoi volume of a collection of atoms also define their surface. The surface of a protein consists of the union of (connected) polyhedra faces. Each face in this surface is shared by one solvent atom and one protein atom (Fig. 22.1.3.2).

Another somewhat related definition is the convex hull, the smallest convex polyhedron that encloses all the atom centres (Fig. 22.1.3.2). This is important in computer-graphics applications and as an intermediary in many geometric constructions related to proteins (Connolly, 1991; O'Rourke, 1994). The convex hull is a subset of the Delaunay triangulation of the surface atoms. It is quickly located by the following procedure (Connolly, 1991): Find the atom farthest from the molecular centre. Then choose two of its neighbours (as determined by the Delaunay triangulation) such that a plane through these three atoms has all the remaining atoms of the molecule on one side of it (the 'plane test'). This is the first triangle in the convex hull. Then one can choose a fourth atom connected to at least two of the three in the triangle and repeat the plane test, and by iteratively repeating this procedure, one can 'sweep' across the surface of the molecule and define the whole convex hull.

Other parts of the Delaunay triangulation can define additional surfaces. The part of the triangulation connecting the first layer of water molecules defines a surface, as does the part joining the second layer. The second layer of water molecules, in fact, has been suggested on physical grounds to be the natural boundary for a protein in solution (Gerstein & Lynden-Bell, 1993*c*). Protein surfaces defined in terms of the convex hull or water layers tend to be 'smoother' than those based on Voronoi faces, omitting deep grooves and clefts (see Fig. 22.1.3.2).

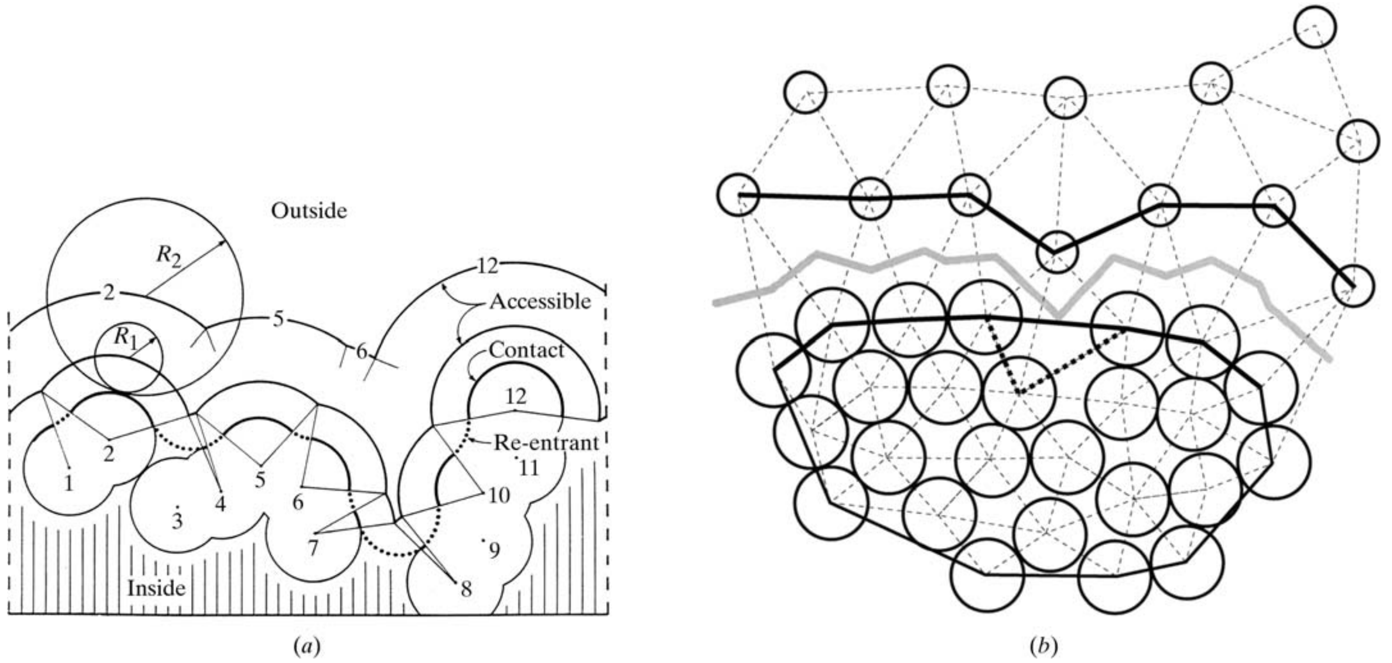

Figure 22.1.3.2
Definitions of the protein surface. (*a*) The classic definitions of protein surface in terms of the probe sphere, the accessible surface and the molecular surface. (This figure is adapted from Richards, 1977). (*b*) Voronoi polyhedra and Delaunay triangulation can also be used to define a protein surface. In this schematic, the large spheres represent closely packed protein atoms and the smaller spheres represent the small loosely packed water molecules. The Delaunay triangulation is shown by dotted lines. Some parts of the triangulation can be used to define surfaces. The outermost part of the triangulation of *just* the protein atoms forms the convex hull. This is indicated by the thick line around the protein atoms. For the convex-hull construction, one imagines that the water is not present. This is highlighted by the thick dotted line, which shows how Delaunay triangulation of the surface atoms in the presence of the water diverges from the convex hull near a deep cleft. Another part of the triangulation, also indicated by thick black lines, connects the first layer of water molecules (those that touch protein atoms). A time-averaged version of this line approximates the accessible surface. Finally, the light thick lines show the Voronoi faces separating the protein surface atoms from the first layer of water molecules. Note how this corresponds approximately to the molecular surface (considering the water positions to be time-averaged). These correspondences between the accessible and molecular surfaces and time-averaged parts of the Voronoi construction are understandable in terms of which part of the probe sphere (centre or point of tangency) is used for the surface definition. The accessible surface is based on the position of the centre of the probe sphere while the molecular surface is based on the points of tangency between the probe sphere and the protein atoms, and these tangent points are similarly positioned to Voronoi faces, which bisect interatomic vectors between solvent and protein atoms.

22.1.3.3. Definitions of surface in terms of a probe sphere

In the absence of solvent molecules to define Voronoi polyhedra, one can define the protein surface in terms of the position of a hypothetical solvent, often called the probe sphere, that 'rolls' around the surface (Richards, 1977) (Fig. 22.1.3.2). The surface of the probe is imagined to be maintained at a tangent to the van der Waals surface of the model.

Various algorithms are used to cause the probe to visit all possible points of contact with the model. The locus of either the centre of the probe or the tangent point to the model is recorded. Either through exact analytical functions or numerical approximations of adjustable accuracy, the algorithms provide an estimate of the area of the resulting surface. (See Chapter 22.2 for a more extensive discussion of the definition, calculation and use of areas.)

Depending on the probe size and whether its centre or point of tangency is used to define the surface, one arrives at a number of commonly used definitions, summarized in Table 22.1.4.1 and Fig. 22.1.3.2.

22.1.3.3.1. van der Waals surface (VDWS)

The area of the van der Waals surface will be calculated by the various area algorithms (see Section 22.2.2 in Chapter 22.2) when the probe radius is set to zero. This is a mathematical calculation only. There is no physical procedure that will measure van der Waals surface area directly. From a mathematical point of view, it is just the first of a set of solvent-accessible surfaces calculated with differing probe radii.

22.1.3.3.2. Solvent-accessible surface (SAS)

The solvent-accessible surface is convex and closed, with defined areas assignable to each individual atom (Lee & Richards, 1971). However, the individual calculated values vary in a complex fashion with variations in the radii of the probe and protein atoms. This radius is frequently, but not always, set at a value considered to represent a water molecule (1.4 Å). The total SAS area increases without bound as the size of the probe increases.

22.1.3.3.3. Molecular surface as the sum of the contact and re-entrant surfaces (MS = CS + RS)

Like the solvent-accessible surface, the molecular surface is also closed, but it contains a mixture of convex and concave patches, the sum of the contact and re-entrant surfaces. The ratio of these two surfaces varies with probe radius. In the limit of infinite probe radius, the molecular surface becomes convex and attains a limiting minimum value (*i.e.* it becomes a convex hull, similar to the one described above). The molecular surface cannot be divided up and assigned unambiguously to individual atoms.

The contact surface is not closed. Instead, it is a series of convex patches on individual atoms, simply related to the solvent-

Table 22.1.4.1
Standard atomic radii (Å)

For '*' see following notes on specific sets of values. *Bondi*: Values assigned on the basis of observed packing in condensed phases (Bondi, 1968). *Lee & Richards*: Values adapted from Bondi (1964) and used in Lee & Richards (1971). *Shrake & Rupley*: Values taken from Pauling (1960) and used in Shrake & Rupley (1973). >C= value can be either 1.5 or 1.85. *Richards*: Minor modification of the original Bondi set in Richards (1974). (Rationale not given.) See original paper for discussion of aromatic carbon value. *Chothia*: From packing in amino-acid crystal structures. Used in Chothia (1975). *Richmond & Richards*: No rationale given for values used in Richmond & Richards (1978). *Gelin & Karplus*: Origin of values not specified. Used in Gelin & Karplus (1979). *Dunfield et al.*: Detailed description of deconvolution of molecular crystal energies. Values represent one-half of the heavy-atom separation at the minimum of the Lennard–Jones 6–12 potential functions for symmetrical interactions. Used in Nemethy *et al.* (1983) and Dunfield *et al.* (1979). *ENCAD*: A set of radii, derived in Gerstein *et al.* (1995), based solely on the *ENCAD* molecular dynamics potential function in Levitt *et al.* (1995). To determine these radii, the separation at which the 6–12 Lennard–Jones interaction energy between equivalent atoms was 0.25 k_BT was determined (0.15 kcal mol^{-1}; 1 kcal = 4.184 kJ). *CHARMM*: Determined in the same way as the *ENCAD* set, but for the *CHARMM* potential (Brooks *et al.*, 1983) (parameter set 19). *Tsai et al.*: Values derived from a new analysis (Tsai *et al.*, 1999) of the most common distances of approach of atoms in the Cambridge Structural Database.

accessible surface of the same atoms. In complementary fashion, the re-entrant surface is also not closed but is a series of concave patches that is part of the probe surface where it contacts two or three atoms simultaneously. At infinite probe radius, the re-entrant areas are plane surfaces, at which point the molecular surface becomes a convex surface. The re-entrant surface cannot be divided up and assigned unambiguously to individual atoms. Note that the molecular surface is simply the union of the contact and re-entrant surfaces, so in terms of area MS = CS + RS.

22.1.3.3.4. *Further points*

The detail provided by these surfaces will depend on the radius of the probe used for their construction.

One may argue that the behaviour of the rolling probe sphere does not accurately model real hydrogen-bonded water. Instead, its 'rolling' more closely mimics the behaviour of a nonpolar solvent. An attempt has been made to incorporate more realistic hydrogen-bonding behaviour into the probe sphere, allowing for the definition of a hydration surface more closely linked to the behaviour of real water (Gerstein & Lynden-Bell, 1993*c*).

The definitions of accessible surface and molecular surface can be related back to the Voronoi construction. The molecular surface is similar to 'time-averaging' the surface formed from the faces of Voronoi polyhedra (the Voronoi surface) over many water configurations, and the accessible surface is similar to averaging the Delaunay triangulation of the first layer of water molecules over many configurations.

There are a number of other definitions of protein surfaces that are unrelated to either the probe-sphere method or Voronoi polyhedra and provide complementary information (Kuhn *et al.*, 1992; Leicester *et al.*, 1988; Pattabiraman *et al.*, 1995).

22.1.4. Definitions of atomic radii

The definition of protein surfaces and volumes depends greatly on the values chosen for various parameters of linear dimension – in particular, van der Waals and probe-sphere radii.

22.1.4.1. *van der Waals radii*

For all the calculations outlined above, the hard-sphere approximation is used for the atoms. (One must remember that in reality atoms are neither hard nor spherical, but this approximation has a long history of demonstrated utility.) There are many lists of the radii of such spheres prepared by different laboratories, both for single atoms and for unified atoms, where the radii are adjusted to approximate the joint size of the heavy atom and its bonded hydrogen atoms (clearly not an actual spherical unit).

Some of these lists are reproduced in Table 22.1.4.1. They are derived from a variety of approaches, *e.g.* looking for the distances of closest approach between atoms (the Bondi set) and energy calculations (the *CHARMM* set). The differences between the sets often come down to how one decides to truncate the Lennard–Jones potential function. Further differences arise

Table 22.1.4.2
Probe radii and their relation to surface definition

The values of 1.4 and, especially, 10 Å are only approximate. One could, of course, use 1.5 Å for a water radius or 15 Å for a ligand radius, depending on the specific application.

Probe radius (Å)	Part of probe sphere	Type of surface
0	Centre (or tangent)	van der Waals surface (VDWS)
1.4	Centre	Solvent-accessible surface (SAS)
1.4	Tangent (one atom)	Contact surface (CS, from parts of atoms)
1.4	Tangent (two or three atoms)	Re-entrant surface (RS, from parts of probe)
1.4	Tangent (one, two, or three atoms)	Molecular surface (MS = CS + RS)
10	Centre	A ligand- or reagent-accessible surface
∞	Tangent	Minimum limit of MS (related to convex hull)
∞	Centre	Undefined

from the parameterization of water and other hydrogen-bonding molecules, as these substances really should be represented with two radii, one for their hydrogen-bonding interactions and one for their VDW interactions.

Perhaps because of the complexities in defining VDW parameters, there are some great differences in Table 22.1.4.1. For instance, the radius for an aliphatic CH (>CH=) ranges from 1.7 to 2.38 Å, and the radius for carboxyl oxygen ranges from 1.34 to 1.89 Å. Both of these represent at least a 40% variation. Moreover, such differences are practically quite significant, since many geometrical and energetic calculations are very sensitive to the choice of VDW parameters, particularly the relative values within a single list. (Repulsive core interactions, in fact, vary almost exponentially.) Consequently, proper volume and surface comparisons can only be based on numbers derived through use of the same list of radii.

In the last column of the table we give a recent set of VDW radii that has been carefully optimized for use in volume and packing calculations. It is derived from analysis of the most common distances between atoms in small-molecule crystal structures in the Cambridge Structural Database (Rowland & Taylor, 1996; Tsai *et al.*, 1999).

22.1.4.2. The probe radius

A series of surfaces can be described by using a probe sphere with a specified radius. Since this is to be a convenient mathematical construct in calculation, any numerical value may be chosen with no necessary relation to physical reality. Some commonly used examples are listed in Table 22.1.4.2.

The solvent-accessible surface is intended to be a close approximation to what a water molecule as a probe might 'see' (Lee & Richards, 1971). However, there is no uniform agreement on what the proper water radius should be. Usually it is chosen to be about 1.4 Å.

22.1.5. Application of geometry calculations: the measurement of packing

22.1.5.1. Using volume to measure packing efficiency

Volume calculations are principally applied in measuring packing. This is because the packing efficiency of a given atom is simply the ratio of the space it could minimally occupy to the space that it actually does occupy. As shown in Fig. 22.1.5.1, this ratio can be expressed as the VDW volume of an atom divided by its Voronoi volume (Richards, 1974, 1985; Richards & Lim, 1994). (Packing efficiency also sometimes goes by the equivalent terms 'packing density' or 'packing coefficient'.) This simple definition masks considerable complexities – in particular, how does one determine the volume of the VDW envelope (Petitjean, 1994)? This requires knowledge of what the VDW radii of atoms are, a

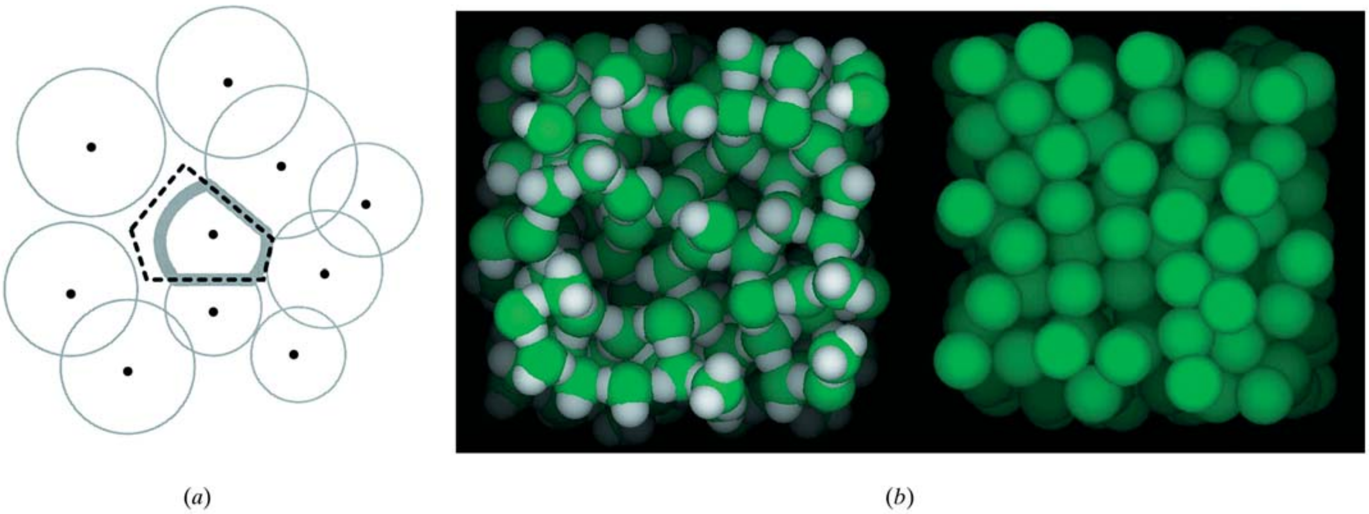

Figure 22.1.5.1
Packing efficiency. (*a*) The relationship between Voronoi polyhedra and packing efficiency. Packing efficiency is defined as the volume of an object as a fraction of the space that it occupies. (It is also known as the 'packing coefficient' or 'packing density'.) In the context of molecular structure, it is measured by the ratio of the VDW volume ($V_{\rm VDW}$, shown by a light grey line) and Voronoi volume ($V_{\rm Vor}$, shown by a dotted line). This calculation gives absolute packing efficiencies. In practice, one usually measures a relative efficiency, relative to the atom in a reference state: $(V_{\rm VDW}/V_{\rm Vor})/[V_{\rm VDW}/V_{\rm Vor}(\text{ref})]$. Note that in this ratio the unchanging VDW volume of an atom cancels out, leaving one with just a ratio of two Voronoi volumes. Perhaps more usefully, when one is trying to evaluate the packing efficiency P at an interface, one computes $P = p\sum V_i/\sum v_i$, where p is packing efficiency of the reference data set (usually 0.74), V_i is the actual measured volume of each atom i at the interface and v_i is the reference volume corresponding to the type of atom i. (*b*) A graphical illustration of the difference between tight packing and loose packing. Frames from a simulation are shown for liquid water (left) and for liquid argon, a simple liquid (right). Owing to its hydrogen bonds, water is much less tightly packed than argon (packing efficiency of 0.35 *versus* ~0.7). Each water molecule has only four to five nearest neighbours while each argon atom has about ten.

Table 22.1.5.1
Standard residue volumes

The mean standard volume, the standard deviation about the mean and the frequency of occurrence of each residue in the protein core are given. Considering cysteine (Cyh, reduced) to be chemically different from cystine (Cys, involved in a disulfide and hence oxidized) gives 21 different residues. These residue volumes are adapted from the *ProtOr* parameter set (also known as the BL+ set) in Tsai *et al.* (1999) and Tsai *et al.* (2001). For this set, the averaging is done over 87 representative high-resolution crystal structures, only buried atoms not in contact with ligands are selected, the radii set shown in the last column of Table 22.1.4.1 is used and the volumes are computed in the presence of the crystal water. The frequencies for buried residues are from Harpaz *et al.* (1994).

Residue	Volume (Å^3)	Standard deviation (Å^3)	Frequency (%)
Ala	89.3	3.5	13
Val	138.2	4.8	13
Leu	163.1	5.8	12
Gly	63.8	2.7	11
Ile	163.0	5.3	9
Phe	190.8	4.8	6
Ser	93.5	3.9	6
Thr	119.6	4.2	5
Tyr	194.6	4.9	3
Asp	114.4	3.9	3
Cys	102.5	3.5	3
Pro	121.3	3.7	3
Met	165.8	5.4	2
Trp	226.4	5.3	2
Gln	146.9	4.3	2
His	157.5	4.3	2
Asn	122.4	4.6	1
Glu	138.8	4.3	1
Cyh	112.8	5.5	1
Arg	190.3	4.7	1
Lys	165.1	6.9	1

subject on which there is not universal agreement (see above), especially for water molecules and polar atoms (Gerstein *et al.*, 1995; Madan & Lee, 1994).

Knowing that the absolute packing efficiency of an atom is a certain value is most useful in a comparative sense, *i.e.* when comparing equivalent atoms in different parts of a protein structure. In taking a ratio of two packing efficiencies, the VDW envelope volume remains the same and cancels. One is left with just the ratio of space that an atom occupies in one environment to what it occupies in another. Thus, for the measurement of packing, standard reference volumes are particularly useful. Recently calculated values of these standard volumes are shown in Tables 22.1.5.1 and 22.1.5.2 for atoms and residues (Tsai *et al.*, 1999).

In analysing molecular systems, one usually finds that close packing is the default (Chandler *et al.*, 1983), *i.e.* atoms pack like billiard balls. Unless there are highly directional interactions (such as hydrogen bonds) that have to be satisfied, one usually achieves close packing to optimize the attractive tail of the VDW interaction. Close-packed spheres of the same size have a packing efficiency of ~0.74. Close-packed spheres of different size are expected to have a somewhat higher packing efficiency. In contrast, water is not close-packed because it has to satisfy the additional constraints of hydrogen bonding. It has an open, tetrahedral structure with a packing efficiency of ~0.35. (This difference in packing efficiency is illustrated in Fig. 22.1.5.1*b*).

22.1.5.2. *The tight packing of the protein core*

The protein core is usually considered to be the atoms inaccessible to solvent *i.e.* with an accessible surface area of zero or a very small number, such as 0.1 Å^2. Packing calculations on the protein core are usually done by calculating the average volumes of the buried atoms and residues in a database of crystal structures. These calculations were first done more than two decades ago (Chothia & Janin, 1975; Finney, 1975; Richards, 1974). The initial calculations revealed some important facts about protein structure. Atoms and residues of a given type inside proteins have a roughly constant (or invariant) volume. This is because the atoms inside proteins are packed together fairly tightly, with the protein interior better resembling a close-packed solid than a liquid or gas. In fact, the packing efficiency of atoms inside proteins is roughly as expected for the close packing of hard spheres (0.74).

More recent calculations measuring the packing in proteins (Harpaz *et al.*, 1994; Tsai *et al.*, 1999) have shown that the packing inside proteins is somewhat tighter (by ~4%) than that observed

Table 22.1.5.2
Standard atomic volumes

Tsai *et al.* (1999) and Tsai *et al.* (2001) clustered all the atoms in proteins into the 18 basic types shown below. Most of these have a simple chemical definition, *e.g.* '=O' are carbonyl carbons. However, some of the basic chemical types, such as the aromatic CH group ('≥CH'), need to be split into two subclusters (bigger and smaller), as is indicated by the column labelled 'Cluster'. Volume statistics were accumulated for each of the 18 types based on averaging over 87 high-resolution crystal structures (in the same fashion as described for the residue volumes in Table 22.1.5.1). No. is the number of atoms averaged over. The final column ('Symbol') gives the standardized symbol used to describe the atom in Tsai *et al.* (1999). The atom volumes shown here are part of the *ProtOr* parameter set (also known as the BL+ set) in Tsai *et al.* (1999).

Atom type	Cluster	Description	Average volume (Å^3)	Standard deviation (Å^3)	No.	Symbol
>C=	Bigger	Trigonal (unbranched), aromatics	9.7	0.7	4184	C3H0b
>C=	Smaller	Trigonal (branched)	8.7	0.6	11876	C3H0s
≥CH	Bigger	Aromatic, CH (facing away from main chain)	21.3	1.9	2063	C3H1b
≥CH	Smaller	Aromatic, CH (facing towards main chain)	20.4	1.7	1742	C3H1s
>CH−	Bigger	Aliphatic, CH (unbranched)	14.4	1.3	3642	C4H1b
>CH−	Smaller	Aliphatic, CH (branched)	13.2	1.0	7028	C4H1s
$-CH_2-$	Bigger	Aliphatic, methyl	24.3	2.1	1065	C4H2b
$-CH_2-$	Smaller	Aliphatic, methyl	23.2	2.3	4228	C4H2s

=O		Carbonyl oxygen	15.9	1.3	7872	O1H0u
−OH		Alcoholic hydroxyl	18.0	1.7	559	O2H1u
−S−		Thioether or –S–S–	29.2	2.6	263	S2H0u
−SH		Sulfhydryl	36.7	4.2	48	S2H1u

initially and that the overall packing efficiency of atoms in the protein core is greater than that in crystals of organic molecules. When molecules are packed this tightly, small changes in packing efficiency are quite significant. In this regime, the limitation on close packing is hard-core repulsion, which is expected to have a twelfth power or exponential dependence, so even a small change is energetically quite substantial. Furthermore, the number of allowable configurations that a collection of atoms can assume without core overlap drops off very quickly as these atoms approach the close-packed limit (Richards & Lim, 1994).

The exceptionally tight packing in the protein core seems to require a precise jigsaw puzzle-like fit of the residues. This appears to be the case for the majority of atoms inside proteins (Connolly, 1986). The tight packing in proteins has, in fact, been proposed as a quality measure in protein crystal structures (Pontius *et al.*, 1996). It is also believed to be a strong constraint on protein flexibility and motions (Gerstein *et al.*, 1993; Gerstein, Lesk & Chothia, 1994). However, there are exceptions, and some studies have focused on these, showing how the packing inside proteins is punctuated by defects, or cavities (Hubbard & Argos, 1994, 1995; Kleywegt & Jones, 1994; Kocher *et al.*, 1996; Rashin *et al.*, 1986; Richards, 1979; Williams *et al.*, 1994). If these defects are large enough, they can contain buried water molecules (Baker & Hubbard, 1984; Matthews *et al.*, 1995; Sreenivasan & Axelsen, 1992).

Surprisingly, despite the intricacies of the observed jigsaw puzzle-like packing in the protein core, it has been shown that one can simply achieve the 'first-order' aspect of this, getting the overall volume of the core right rather easily (Gerstein, Sonnhammer & Chothia, 1994; Kapp *et al.*, 1995; Lim & Ptitsyn, 1970). This has to do with simple statistics for summing random numbers and the fact that the distribution of sizes for amino acids usually found inside proteins is rather narrow (Table 22.1.5.1). In fact, the similarly sized residues Val, Ile, Leu and Ala (with volumes 138, 163, 163 and 89 Å^3) make up about half of the residues buried in the protein core. Furthermore, aliphatic residues, in particular, have a relatively large number of adjustable degrees of freedom per Å^3, allowing them to accommodate a wide range of packing geometries. All of this suggests that many of the features of protein sequences may only require random-like qualities for them to fold (Finkelstein, 1994).

22.1.5.3. Looser packing on the surface

Measuring the packing efficiency inside the protein core provides a good reference point for comparison, and a number of other studies have looked at this in comparison with other parts of the protein. The most obvious thing to compare with the protein inside is the protein outside, or surface. This is particularly interesting from a packing perspective, since the protein surface is covered by water, and water is packed much less tightly than protein and in a distinctly different fashion. (The tetrahedral packing geometry of water molecules gives a packing efficiency of less than half that of hexagonal close-packed solids.)

Calculations based on crystal structures and simulations have shown that the protein surface has intermediate packing, being packed less tightly than the core but not as loosely as liquid water (Gerstein & Chothia, 1996; Gerstein *et al.*, 1995). One can understand the looser packing at the surface than in the core in terms of a simple trade-off between hydrogen bonding and close packing, and this can be explicitly visualized in simulations of the packing in simple toy systems (Gerstein & Lynden-Bell, 1993*a*,*b*).

Chapter 22.2. Molecular surfaces: calculations, uses and representations

M. S. Chapman and M. L. Connolly

22.2.1. Introduction

22.2.1.1. Uses of surface-area calculations

Interactions between molecules are most likely to be mediated by the properties of residues at their surfaces. Surfaces have figured prominently in functional interpretations of macromolecular structure. Which residues are most likely to interact with other molecules? What are their properties: charged, polar, or hydrophobic? What would be the estimated energy of interaction? How do the shapes and properties complement one another? Which surfaces are most conserved among a homologous family? At the centre of these questions that are often asked at the start of a structural interpretation lies the calculation of the molecular and/or accessible surfaces.

Surface-area calculations are used in two ways. Graphical surface representations help to obtain a quick intuitive understanding of potential molecular functions and interactions through visualization of the shape, charge distribution, polarity, or sequence conservation on the molecular surface (for example). Quantitative calculations of surface area are used *en route* to approximations of the free energy of interactions in binding complexes.

Part of this subject area was the topic of an excellent review by Richards (1985), to which the reader is referred for greater coverage of many of the methods of calculation. This review will attempt to incorporate more recent developments, particularly in the use of graphics, both realistic and schematic.

22.2.1.2. Molecular, solvent-accessible and occluded surface areas

The concept of molecular surface derives from the behaviour of non-bonded atoms as they approach each other. As indicated by the Lennard–Jones potential, strong unfavourable interactions of overlapping non-bonding electron orbitals increase sharply according to $1/r^{12}$, and atoms behave almost as if they were hard spheres with *van der Waals* radii that are characteristic for each atom type and nearly independent of chemical context. Of course, when orbitals combine in a covalent bond, atoms approach much more closely. Lower-energy attractions between atoms, such as hydrogen bonds or aromatic ring stacking, lead to modest reductions in the distance of closest approach. The van der Waals surface is the area of a volume formed by placing van der Waals spheres at the centre of each atom in a molecule.

Non-bonded atoms of the same molecule contact each other over (at most) a very small proportion of their van der Waals surface. The surface is complicated with gaps and crevices. Much of this surface is inaccessible to other atoms or molecules, because there is insufficient space to place an atom without resulting in forbidden overlap of non-bonded van der Waals spheres (Fig. 22.2.1.1). These crevices are excluded in the *molecular surface area*. The molecular surface area, also known as the solvent-excluding surface, is the outer surface of the volume from which solvent molecules are excluded. Strictly, this would depend on the orientation of non-spherically symmetric solvents such as water. However, since hydrogen atoms are smaller than oxygen atoms, for current purposes it is sufficient to consider water as a sphere with a radius of 1.4 to 1.7 Å, approximating the 'average' distance from the centre of the oxygen atom to the van der Waals surface of water. The practical definition of the molecular surface is, then, the area of the volume excluded to a spherical probe of 1.4 to 1.7 Å radius.

As an aside, it is important to note that surface-area calculations depend on inexact parameterization. For example, there is no radius of any hard-sphere model that can give a realistic representation of the solvent. Furthermore, the choice of van der Waals radii can depend on whether the distance of zero or minimum potential energy is estimated and the potential-energy function or experimental data used. (Tables of common values are given by Gerstein & Richards in Chapter 22.1.) Thus, calculations of molecular and accessible surfaces are approximate. However, when the errors are averaged over large areas of a macromolecule, the numbers can be precise enough to give important insights into function.

Fig. 22.2.1.1 shows that the molecular surface consists of two components. The contact surface is part of the van der Waals surface. The re-entrant surface encloses the interstitial volume and has components that are the exterior surfaces of atoms (contact surface) and parts of the surfaces of probes placed in positions where they are in contact with van der Waals surfaces of two or more atoms (re-entrant surface).

The occluded molecular surface is an approximate complement to the solvent-accessible surface. It is the part of the surface that would be inaccessible to solvent because of steric conflict with neighbouring macromolecular atoms. It is an approximation in that current calculations use van der Waals surfaces, ignoring the differences between atomic and re-entrant surfaces (see below), and the volume of the probe is not fully accounted for (Pattabiraman *et al.*, 1995). Occluded area is defined as the atomic area whose normals cannot be extended 2.8 Å (the presumptive diameter of a water molecule) without intersecting the van der Waals volume of another atom. This crude approximation to the surface that is inaccessible to water not only

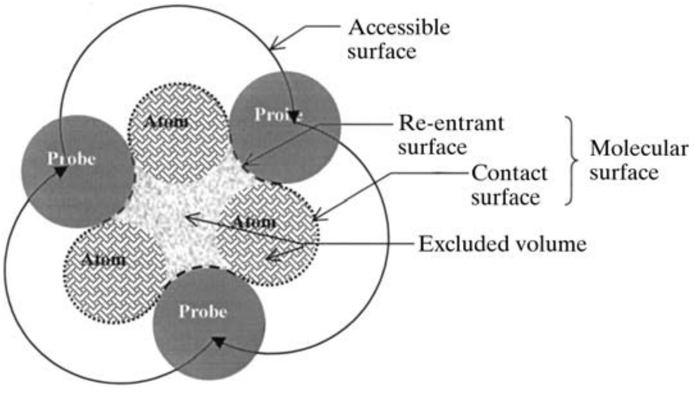

Figure 22.2.1.1
Surfaces in a plane cut through a hypothetical molecule. The molecular surface consists of the sum of the atomic surfaces that can be contacted by solvent molecules and the surface of the space between atoms from which solvent molecules are excluded. The solvent-accessible surface is the surface formed by the set of the centres of spheres that are in closest contact with the molecular surface.

Copyright © 2012 International Union of Crystallography

increases the speed of calculation, but enables surface areas to be partitioned between the atoms. It is used primarily to evaluate model protein structures by comparing the fraction of each amino acid's surface area that is occluded with that calculated for the same residue types in a database of accurate structures.

22.2.1.3. Hydration surface

Whether graphically displaying a molecule or examining potential docking interactions, it is usually the molecular surface or solvent-accessible surface that is used. However, macromolecules also interact through the small (solvent) molecules that are more or less tightly bound (Gerstein & Lynden-Bell, 1993). There is a gradation of how tightly solvent molecules are bound and how many are bound around different side chains. With dynamics simulations, Gerstein & Lynden-Bell (1993) showed that the second hydration shell was a reasonable, practical 'average' limit to which water atoms should be considered significantly perturbed by the protein. They defined a hydration surface as the surface of this second shell and presented evidence that it approximates the boundary between bound and bulk solvent. They presented calculations that showed that molecules interact significantly when their hydration surfaces interact, and not just when they are close enough for their molecular surfaces to form contacts. It may be computationally impractical to perform the simulations required to calculate the hydration surfaces of many proteins, but this work reminds us that energetically significant interactions occur over a wider area than the commonly computed contact molecular-surface area.

22.2.1.4. Hydrophobicity

The hydrophobic effect (Kauzmann, 1959; Tanford, 1997) has its origins in unfavourable entropic terms for water molecules immediately surrounding a hydrophobic group. In the bulk solvent, each water molecule can be oriented in a variety of ways with favourable hydrogen bonding. At the interface with a hydrophobic group, hydrogen bonds are possible only in some directions, with some configurations of the water molecules. When a hydrophobic group is embedded in water, the surrounding solvent molecules have a more restricted set of hydrogen-bonding configurations, resulting in an unfavourable entropic term. The magnitude of the entropic term should be proportional to the number of solvent molecules immediately surrounding the hydrophobic group. This integer number can be considered very approximately proportional to the area of the surface made by the centres of the set of possible solvent probes contacting the solute, *i.e.* the *solvent-accessible surface area* (Fig. 22.2.1.1). When large areas are considered, summed over many hydrophobic atoms, the errors of this non-integer approximation are insignificant. It is now common practice to estimate the hydrophobic effect free-energy contribution by multiplying the change in macromolecular surface area by an energy per unit area [~80 J mol^{-1} Å^{-2} (Richards, 1985), but see also below].

22.2.2. Calculation of surface area and energies of interaction

22.2.2.1. Introduction

The first method to be discussed allows the calculation of an accessible surface. The first method for calculating molecular surface involved raining water down on a model of a macromolecule and constructing a surface by making a net under the spheres in their landing positions (Greer & Bush, 1978). This ignored overhangs and was replaced by the dot surface method. More recently, methods were developed to make polyhedral surfaces of triangles by contouring between lattice points or by delimiting with arcs the spherical and toroidal surfaces and then subdividing the piece-wise quartic molecular surface. The surface is then composed of patches whose areas can be precisely integrated. van der Waals surfaces consist of convex spherical triangles whose areas can be estimated by the Gauss–Bonnet theorem. Re-entrant surfaces are comprised of concave spherical triangles whose areas can be similarly estimated and toroidal saddle-shaped patches whose areas can be calculated by analytical geometry and calculus.

22.2.2.2. Lee & Richards planar slices

The first method for calculating the accessible surface area overlaid the molecule on a regular stack of finely spaced parallel planes (Lee & Richards, 1971). The advantage of this method was the ease with which the area could be calculated. The intersection of the atomic surfaces with the planes were circular arcs whose lengths were readily calculated and multiplied by the planar spacing to give an approximation to the surface area. Programs that are currently distributed use more sophisticated methods.

22.2.2.3. Connolly dot surface algorithm

A molecular dot surface is a smooth envelope of points on the molecular surface. A probe sphere is placed at a set of approximately evenly spaced points so that the probe and van der Waals surfaces of a given atom are tangential. If the probe sphere does not overlap any other atom, the point is designated as surface. To define the re-entrant surface, sphere centres are also sampled that are tangential to both van der Waals spheres of a pair of neighbouring atoms and are equidistant from the interatomic axis. Arcs are then drawn between surface points and the arcs are subdivided into a set of finely spaced points to define the re-entrant surface. Similarly, spheres contacting triplets of neighbouring atoms are tested, and approximately evenly spaced points within the concave triangle defined by the three contact points are added to the re-entrant surface.

22.2.2.4. Marching-cube algorithm

This is conceptually the simplest method and is used in the program *GRASP* (Nicholls *et al.*, 1991). First, grid points of a cubic lattice overlaid on the molecule are segregated into 'interior' and 'exterior' as follows. All points farther from an atom than the sum of the van der Waals radius and a probe radius are flagged as external. External points with an internal neighbour are flagged as an approximate 'accessible surface'. All grid points falling within probe spheres centred at each surface point now join the set of exterior points. Points that remain 'interior' define the volume enclosed by the molecular surface.

All that remains is to contour the molecular surface that lies between interior and exterior grid points. It is a little complicated in three dimensions and is achieved by the marching-cube algorithm. Cubes containing adjacent grid points that are both interior and exterior are used to define potential polyhedral vertices. Triangles are defined by joining the midpoints of unit-cell edges that have one interior and one exterior point. The triangles are joined at their edges in a consistent manner to create a polyhedral surface.

22.2.2.5. Complete and connected rolling algorithms

Several algorithms start by dividing the surface into regions within which the surface is smooth and continuous. The surface can be efficiently described in terms of a set of arcs and their start and end points. In complete rolling, the probe is placed in all possible positions at which it contacts the van der Waals spheres of three neighbouring atoms. Those surrounding the same atom are paired as the start and end points of an arc. The complete rolling algorithm does not distinguish outer and inner (cavity) surfaces. In the connected rolling algorithm, the process starts at a triple contact point that is far from the centre of mass and therefore likely to be external. The probe is then rolled only along crevices between two atoms, pursuing all alternatives, stopping each pathway only when the probe returns to a place that has already been probed. This algorithm therefore produces only the outer surface.

22.2.2.6. Analytic surface calculations and the Gauss–Bonnet theorem

An analytical method was also proposed for calculating approximate accessible areas (Wodak & Janin, 1980). It assumed random distributions of neighbouring atoms, but this can be a sufficient approximation when calculating the area of an entire molecule. The areas of spherical and toroidal pieces of surface can be calculated exactly by analytic and differential geometry (Richmond, 1984; Connolly, 1983). An advantage of analytical expressions over the prior numerical approximations is that analytical derivatives of the areas can be calculated, albeit with significant difficulty. This then provides the opportunity to optimize atomic positions with respect to surface area. Pseudo-energy functions that approximate the hydrophobic contribution to free energy with a term proportional to the accessible surface area (Richards, 1977) can therefore be incorporated in energy-minimization programs. Although rigorous, these methods are computationally cumbersome and are not used in all energy-minimization routines. Incorporation of solvent effects may become more universal with the Gaussian atom approximations discussed below.

22.2.2.7. Approximations to the surface

The methods discussed above are computationally quite cumbersome, especially if they need to be repeated many times. Thus, they are not well suited to comparisons of many structures. They are also not well suited to the calculation of surface-area-dependent energy terms during dynamics simulation or energy minimization, which require the calculation of the derivatives of the surface area with respect to atomic position. It has been argued by several (including A. Nicholls and K. Sharp, personal communications) that simplifying approximations to the surface-area calculations are in order, because the common uses of surface area already embody crude *ad hoc* approximations, such as non-integer numbers of spherical solvent molecules.

In the treatments discussed earlier, the volume of the protein is (implicitly) described by a set of overlapping step functions that have a constant value if close enough to an atom, or zero if not. Several authors have replaced these step functions with continuous spherical Gaussian functions centred on each atom (Gerstein, 1992; Grant & Pickup, 1995) in treatments reminiscent of Ten Eyck's electron-density calculations (Ten Eyck, 1977). This speeds up the calculation and also facilitates the calculation of analytical derivatives of the surface area. A surface can be calculated for graphical display by contouring the continuous function at an appropriate threshold. The final envelope can be modified by using iterative procedures that fill cavities and crevices that are (nearly) surrounded by protein atoms (Gerstein, 1992).

Table 22.2.3.1
The atomic solvation parameters of Eisenberg & McLachlan (1986)

Atom	$\Delta\sigma$(atom) (J mol^{-1} Å^{-2})
C	67 (8)
N/O	−25 (17)
$O^{\cdot\cdot}$	−101 (42)
N^{+}	−210 (38)
S	88 (42)

22.2.2.8. Extended atoms account for missing hydrogen atoms

Structures of macromolecules determined by X-ray crystallography rarely reveal the positions of the hydrogen atoms. It is, of course, possible to add explicit hydrogen atoms at the stereochemically most likely positions, but this is rarely done for surface-area calculations. Instead, their average effect is approximately and implicitly accounted for by increasing the heteroatom van der Waals radius by 0.1 to 0.3 Å. (It is not usual to smear atoms to account for thermal motion.)

22.2.3. Estimation of binding energies

22.2.3.1. Hydrophobicity

As previously introduced, hydrophobic energies result primarily from the increased entropy of water molecules at the macromolecule–solvent interface and can be estimated from the accessible surface area. A number of different constants relating area to free energy of transfer from a hydrophobic to aqueous environment have been proposed in the range of 67 to 130 J mol^{-1} Å^{-2} (Reynolds *et al.*, 1974; Chothia, 1976; Hermann, 1977; Eisenberg & McLachlan, 1986), but if a single value is to be used for all of the protein surface, the consensus among crystallographers has been about 80 J mol^{-1} Å^{-2} (Richards, 1985).

There are two widely used enhancements of the basic method. Atomic solvation parameters (ASPs, $\Delta\sigma$) remove the assumption that all protein atoms have equal potential influence on the hydrophobic free energy. Eisenberg & McLachlan (1986) determined separate ASPs for atom types C, N/O, $O^{\cdot\cdot}$, N^{+} and S (treating hydrogen atoms implicitly) by fitting these constants to the experimentally determined octanol/water relative transfer free energies of the 20 amino-acid side chains of Fauchere & Pliska (1983), assuming standard conformations of the side chains. A much improved free energy change of solvation can then be estimated from $\Delta G = \sum_{\mathrm{atoms}\, i} \Delta\sigma_i A_i$, where the summation is over all atoms with accessible area A and $\Delta\sigma_i$ is specific for the atom type. Their estimates of ASPs are given in Table 22.2.3.1. Use of ASPs rather than a single value for all atoms makes substantial differences to the estimated free energies of association of macromolecular assemblies (Xie & Chapman, 1996). Through calculation of the overall energy of solvation, calculations with ASPs also allow discrimination between proposed structures that are correctly folded (with hydrophobic side chains that are predominantly internal) and those that are not (Eisenberg & McLachlan, 1986).

The work of Sharp *et al.* (1991) indicates that hydrophobicity depends not only on surface area, but curvature. Sharp *et al.* were trying to reconcile long-apparent differences between microscopic and macroscopic measurements of hydrophobicity (Tanford, 1979). Microscopic measurements, the basis of all of our preceding discussions, are derived from the partitioning of dilute solutes between solvents. Macroscopic values can come from the measurements of the surface tension between a liquid bulk of the molecule of interest and water. Macroscopic values for aliphatic carbons are much higher, ~302 J mol^{-1} Å^{-2}. Postulating that the entropic effects at the heart of hydrophobicity depended on the number of water molecules in contact with each other at the molecular surface (Nicholls *et al.*, 1991), Sharp *et al.* pointed out that not all surfaces were equivalent. Relative to a plane, concave solute surfaces would accommodate fewer solvent molecules neighbouring the molecular surface, whereas convex surfaces would accommodate more. Their treatment could be considered to be a second-order approximation to the number of interfacial solvent molecules, compared to the prior first-order consideration of only area.

To calculate the curvature of point *a* on the accessible surface (relative to that of a plane), a sphere of twice the solvent radius is drawn (Nicholls *et al.*, 1991). This represents the locus of the centres of solvent molecules that could be in contact with a solvent at *a*. A curvature correction, *c*, is the proportion of points on the spherical surface that are inside the inaccessible volume, relative to that for a planar accessible surface ($\frac{1}{2}$). In calculating the free energy of transfer, each element of the accessible area is multiplied by its curvature correction. When this is done, the increasingly convex surfaces of small aliphatic molecules account for most of the discrepancy between microscopic and macroscopic hydrophobicities (Nicholls *et al.*, 1991). Furthermore, it emphasizes that, just by their shape, concave surfaces can become relatively hydrophobic. This has been clearly illustrated with *GRASP* surface representations (see below) in which the accessible surface is coloured according to the local curvature (Nicholls *et al.*, 1991). Consideration of curvature also indicates that the energy of macromolecular association is slightly less than it would otherwise be due to the generation of a concave collar at the interface between two binding macromolecules (Nicholls *et al.*, 1991).

22.2.3.2. *Estimates of binding energies*

In a molecular association in which (as is often the case) hydrophobic interactions dominate, the binding energy can be estimated from the surfaces of the individual molecules that become buried upon association (Richards, 1985). The buried area is simply the sum of the surfaces of the two molecules (calculated independently) minus the surface of the complex, calculated as if one molecule. Usually, all heteroatoms are regarded as equivalent, and the buried area is multiplied by a uniform constant, say 80 J mol^{-1} Å^{-2} (Richards, 1985). It is only slightly more complicated to use the different ASPs (Eisenberg & McLachlan, 1986) for different atom types and/or to account for curvature (Nicholls *et al.*, 1991). It should be noted that in many crystal structures, the distinction between atom types in some side chains remains indeterminate, *e.g.* N and C in histidines, O and O$^{\cdot\cdot}$ in carboxylates, and N and N^{+} in arginines. In such cases, average values of the two ASPs can be used (Xie & Chapman, 1996). Such energy calculations have been put to several uses, including attempts to predict assembly and disassembly pathways for viral capsid assemblies (Arnold & Rossmann, 1990; Xie & Chapman, 1996, and citations therein).

22.2.3.3. *Other non-graphical interpretive methods using surface area*

Which are the amino acids most likely to interact with other molecules? It is reasonable to expect them to be surface-accessible. In determining which residues are most surface-exposed, it is necessary to partition molecular or accessible surfaces between atoms. Contact surfaces (Fig. 22.2.1.1) are atom specific. Re-entrant or accessible surfaces can be divided among surface atoms by proximity. Surface areas can then be summed over the atoms in a residue. Accessible surface areas are sometimes reported as *accessibilities* (Lee & Richards, 1971) – fractions of a maximum where the standard is evaluated from a tripeptide in which the residue of interest is surrounded by glycines. A different approach to assessing surface exposure is to ask what is the largest molecular fragment that could contact a given atom. This is commonly assayed by determining the largest sphere that can be placed tangentially to the van der Waals surface without intersecting any other atom. An alternative approach to locating functionally important surface regions was proposed in the mid-1980s, but is currently not used very often. The local irregularity of surface texture was characterized through measurement of the fractal dimension (Lewis & Rees, 1985).

Substrates, drugs and ligands often bind in clefts or pockets that are concave in shape. Conversely, it is the most exposed convex regions that are likely to be antigenic. The surface shape can be determined by placing a large (say 6 Å radius) sphere at each vertex of the polyhedral molecular surface. If more than half of the sphere's volume overlaps the molecular volume, then the surface is concave, while if less than half, the surface is convex.

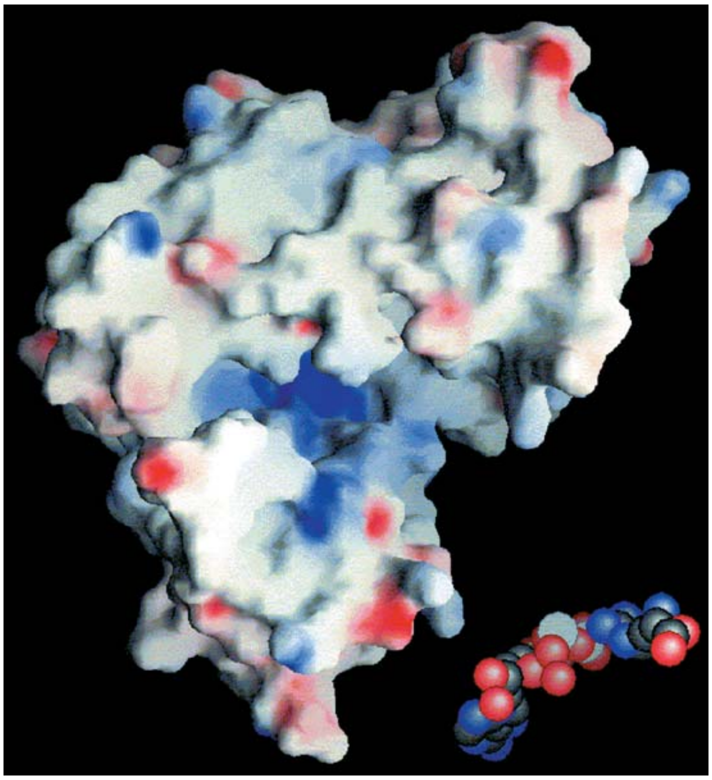

Figure 22.2.4.1
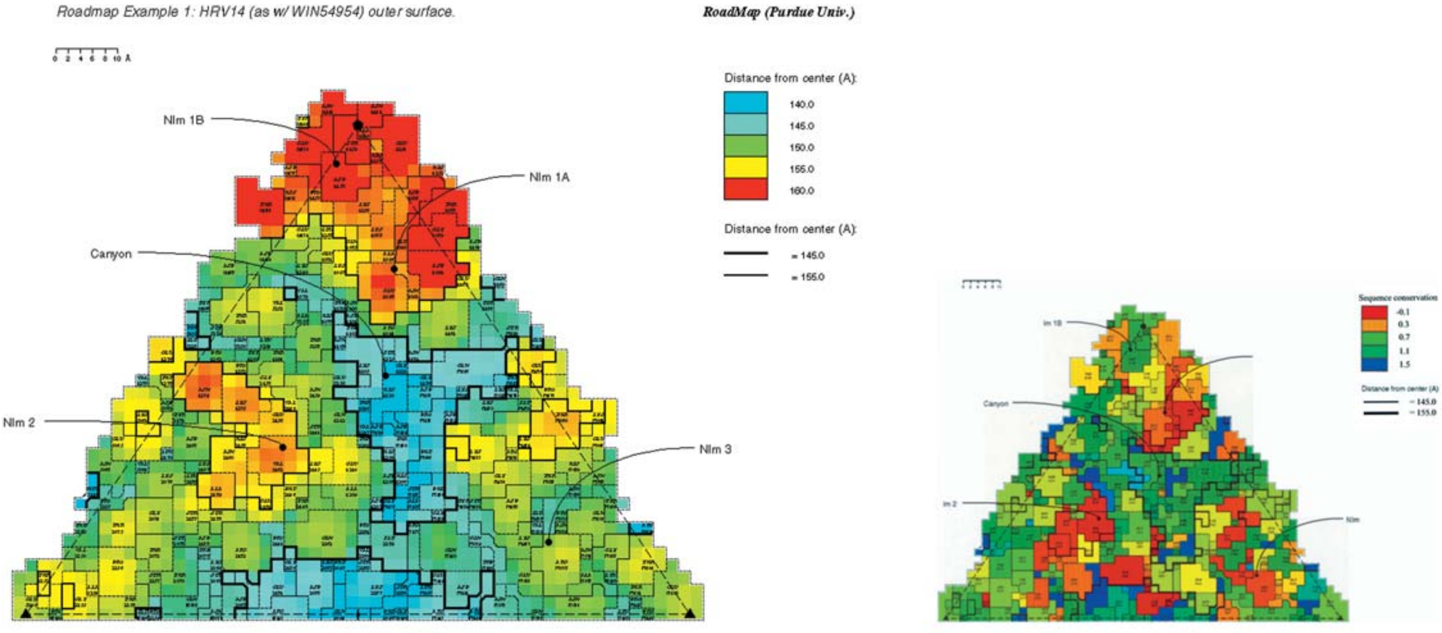
GRASP example. The larger picture shows the molecular surface of arginine kinase (Zhou *et al.*, 1998) with the domains and a loop moved to the open configuration seen in a homologous creatine kinase structure (Fritz-Wolf *et al.*, 1996). The surface, coloured with positive charge blue and negative charge red, demonstrates that the active-site pocket (centre) is the most positively charged part of the structure. It complements the negatively charged phosphates of the transition-state analogue components that are shown, moved as a rigid body to the bottom right. They are shown in van der Waals representation, in which oxygens are red, carbons black and nitrogens blue.



(*a*) (*b*)

Figure 22.2.4.2

(*a*) Solvent-accessible surface topology of a rhinovirus 14–drug complex (Kim *et al.*, 1993). The triangle shows one of the 60 symmetry-equivalent faces of an icosadeltahedron that constitute the entire virus surface. The surface is coloured and contoured according to distance from the centre of the virus, red being the most elevated. Residues are marked with dotted lines and labelled with residue type and number. A letter starting the residue label indicates a symmetry equivalent. The first numeral indicates the protein number (1 to 4), which is followed by the three-digit residue number. A depression, the 'canyon', is where the cellular receptor is bound (Olson *et al.*, 1993). The locations of the dominant neutralizing immunogenic (NIm) sites were determined through the sequencing of escape mutants (Sherry & Rueckert, 1985; Sherry *et al.*, 1986) and are labelled 'NIm'. (*b*) The same view is coloured according to sequence similarity (Palmenberg, 1989; Chapman, 1994), with blue being the most conserved rhinoviral amino acids and red being the most variable. Comparison of diagrams like these suggested the 'canyon hypothesis' (Rossmann, 1989). The prediction has proved largely true in that the sites of receptor attachment in several picornaviruses would be depressed areas whose sequences could be more highly conserved because they were partially inaccessible to antibodies and therefore not under the same selective pressure to mutate. In this and other applications, the schematic nature of these diagrams has helped in the collation of structure with data arising from the known phenotypes of site-directed or natural mutants. Part (*b*) is reproduced from Chapman (1993). Copyright (1993) The Protein Society. Reprinted with the permission of Cambridge University Press.

Are there similarities in the shapes of surfaces at the interfaces of macromolecular complexes? For example, are there similarities between the shapes of evolutionary-related antigens or the hypervariable regions of antibodies that bind to them? Quantitative comparison of surface topologies is far from trivial, with questions of three-dimensional (3D) alignment, the metrics to be used in quantifying topology *etc.* In addition to real differences between molecules, their surfaces may appear to differ due to the resolutions at which their structures were determined. Gerstein (1992) has proposed that comparisons be made in reciprocal space so that correlations can be judged as a function of resolution. Coordinates are aligned. Spherical Gaussian functions are placed at each atom, and an envelope is calculated at some threshold value and modified to remove cavities. Gerstein found that comparison of the envelope structure-factor vectors, obtained by Fourier transformation, led to a plausible classification of the hypervariable regions of known antibody structures.

22.2.4. Graphical representations of shape and properties

22.2.4.1. *Realistic*

22.2.4.1.1. *Shaded backbone*

With very large complexes, such as viruses, the surface features to be viewed are obvious at low resolution. In a very simple yet effective representation popularized by the laboratories of David Stuart and Jim Hogle, a Cα trace is 'depth cued' (shaded) according to the distance from the centre of mass (Acharya *et al.*, 1990; Fig. 1 for example). The impression of three dimensions probably results from the similarity of the shading to highlighting. The method is most effective for large complexes in which there are sufficient Cα atoms to give a dense impression of a surface.

22.2.4.1.2. *'Connolly' and solid polyhedral surfaces*

In one of the earliest surface graphical representations, dots were drawn for each Connolly surface dot, using vector-graphics terminals. With the improved graphics capability of modern computers, dot representations have been replaced by ones in which solid polyhedra are drawn with a large enough number of small triangular faces such that the surface appears smooth. These representations are clearer, because atoms in the foreground obscure those in the background.

22.2.4.1.3. *Photorealistic rendering*

Depth and three-dimensional relationships are most easily represented by stereovision or rotation of objects in real time on a computer screen. Graphics engines for interactive computers compromise quality for the speed necessary for interactive response, but simple depth cueing (combined with motion or stereo) is sufficient for good 3D representation. For still and/or non-stereo images more common in publications, more sophisticated rendering is helpful and possible now that speed is not a constraint. In *Raster3D* (Merritt & Bacon, 1997), multiple-light-source shading and highlighting is added, with individual calculations for each fine pixel. These are dependent on the directions

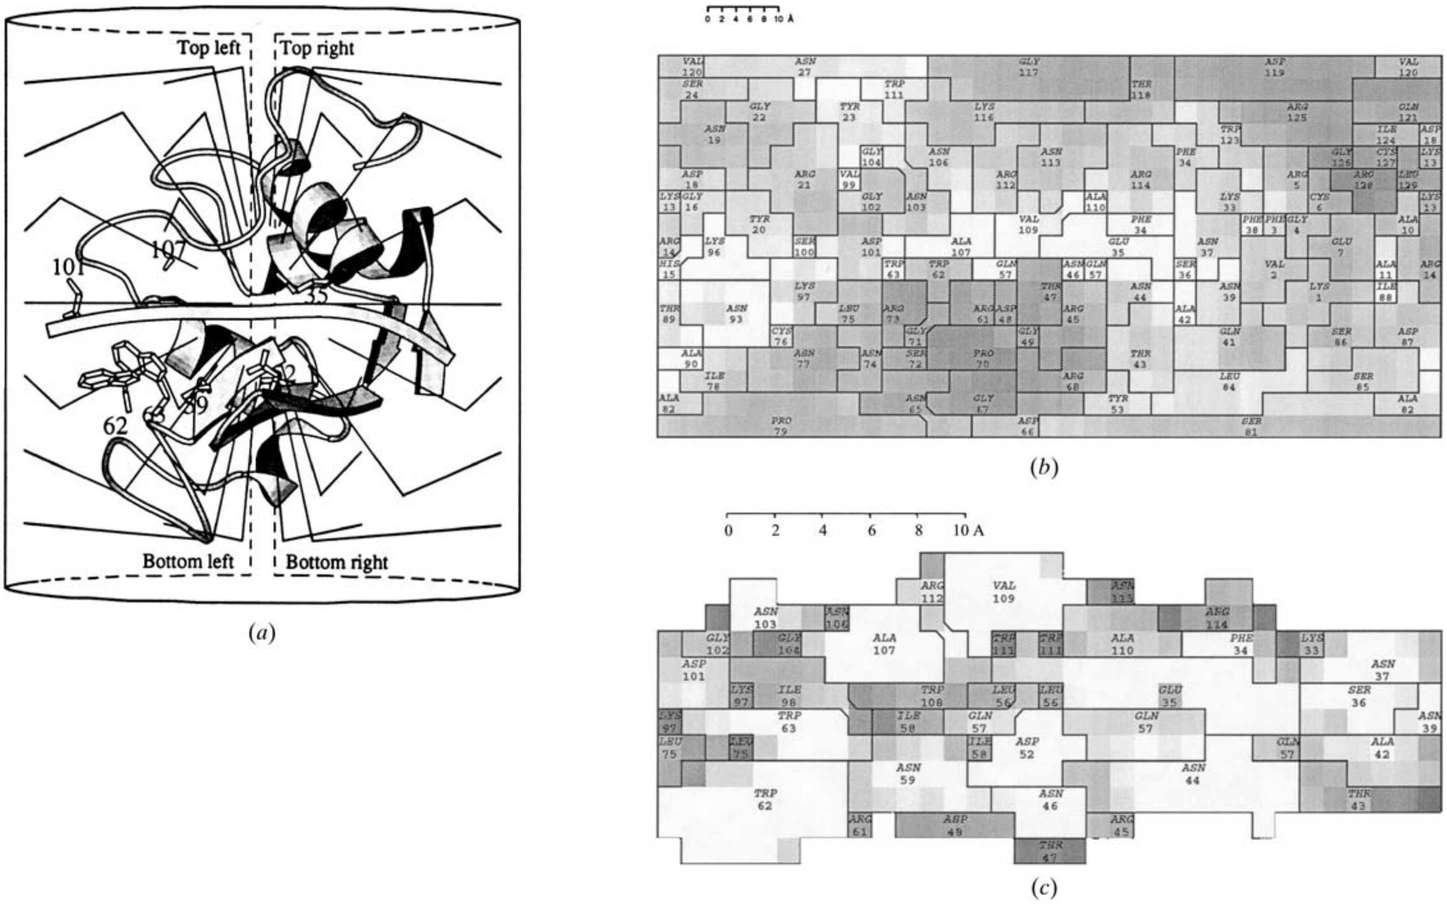


Figure 22.2.4.3

Different projections illustrated with lysozyme. (*a*) Lysozyme (Blake *et al.*, 1965; Diamond, 1974) is sketched with *MOLSCRIPT* (Kraulis, 1991) and shown with a ribbon indicting the active-site cleft (Kelly *et al.*, 1979). A cylindrical surface shown unrolled in (*b*) is shown in (*a*) wrapped around lysozyme. Vectors orthogonal to the now cylindrical illustrative surface are extended inwards until they intersect with the sphere. Vectors then run towards the centre of the molecule, and their intersections with the solvent-accessible surface are projected back upon the cylinder [unrolled in (*b*)]. (*b*) The surface is shaded according to distance from the centre, revealing the substrate-binding cleft as lighter shading. Details of active-site residues are revealed in (*c*) with a different type of projection. A segmented bent cylinder was traced along the substrate-binding cleft. The surface shows the projection outwards from points on the cylindrical axis. This reveals the amino acids likely to be in most intimate contact with the substrate. Similar plots, coloured according to charge, atomic solvation parameters, or hydrophobicity, can reveal the nature of predominant chemical interactions. This figure is reproduced from Chapman (1993). Copyright (1993) The Protein Society. Reprinted with the permission of Cambridge University Press.

of the normals to the surface, which are calculated analytically for spherical surfaces. More complicated surfaces, input as connected triangles, have surfaces rendered raster, pixel by pixel, by interpolating between the surface-normal vectors at the vertices of the surrounding triangle. Together, this leads to a high-quality smooth image that conveys much of the three-dimensionality of molecular surfaces.

22.2.4.1.4. GRASP surfaces

GRASP is currently perhaps the most popular program for the display of molecular surfaces. Readers are referred to the program documentation (Nicholls, 1992) or a paper that tangentially describes an early implementation (Nicholls *et al.*, 1991). The molecular or accessible surface is determined by the marching-cube algorithm. The surface is filled using methods that make modest compromises on photorealistic light reflection *etc.*, but take advantage of machine-dependent Silicon Graphics surface rendering to perform the display fast enough for interactive adjustment of the view.

The most powerful part of the program is the ability to colour according to properties mapped to the surface (see Fig. 22.2.4.1). These may be values of (say) electrostatic potential interpolated from a three-dimensional lattice. Much has been learned about many proteins from the potentials determined by solution of the Poisson–Boltzmann equation (Nicholls & Honig, 1991). The electrostatic complementarity of binding surfaces has often been readily apparent in ways that were not obvious from Coulombic calculations that ignore screening or from calculations and graphics representations that treat the charges of individual atoms as independent entities.

Many other properties can be mapped to the surface. These include properties of the atoms associated with that part of the surface (such as thermal factors), curvature of the surface calculated from adjacent atoms (Nicholls & Honig, 1991), or distance to the nearest part of the surface of an adjacent molecule. *GRASP* is now used to illustrate complicated molecular structures, in part because it also supports the superimposition of other objects over the molecular surface. These include the representation of molecules with Corey–Pauling–Koltun (CPK) spheres and/or bonds, and the representation of electrostatic potentials with field lines, dipole vectors *etc.*

22.2.4.1.5. Implementations in popular packages

Commercial packages use variants of the methods discussed above. For example, surfaces are drawn in the *Insight II* molecular modelling system using the Connolly dot algorithm (Molecular Structure Corporation, 1995).

22.2.4.2. *Schematic and two-dimensional representations such as 'roadmap'*

For their work on viruses, Rossmann & Palmenberg (1988) introduced a highly schematic representation in which individual amino acids were labelled. The methods were extended by Chapman (1993) to other proteins and to the automatic display of features such as topology, sequence similarity and hydrophobicity. Roadmaps sacrifice a realistic impression of shape for the ability to show the locations and properties of constituent surface atoms or residues. This has been important in combining the power of structure and molecular biology in understanding function. Potential sites of mutation are readily identified without substantial molecular-graphics resources, and phenotypes of mutants are readily mapped to the surface and compared with the physiochemical properties to reveal structure–function correlations.

For a set of projection vectors, the intersection points with the first van der Waals (or solvent-accessible) surface of an atom are calculated by basic vector algebra. The atom is identified so that when the projection is mapped to a plane for display, the boundaries of each atom or amino acid can be determined. The atoms or amino acids can then be coloured, shaded, outlined, contoured, or labelled according to parameters that are either calculated from the coordinates (such as distance from the centre of mass), read from a file (such as sequence similarity), or follow properties that are dependent on the residue type (*e.g.* hydrophobicity) or atom type [*e.g.* atomic solvation parameters (Eisenberg & McLachlan, 1986)].

Several types of projections can be used. The simplest is similar to that used by most other surface-imaging programs. A set of parallel projection vectors is mapped to a 2D grid. An example is shown in Fig. 22.2.4.2. This view avoids distortions, but only one side of the molecule is visualized. Roadmaps are flat, two-dimensional projections that cannot be rotated in real time to reveal other views. Three-dimensionality is limited to an extension by Jean-Yves Sgro that maps the parallel projection of one view to a three-dimensional surface shell that can be rotated with interactive graphics and/or viewed with stereo imaging (Harber *et al.*, 1995; Sgro, 1996). However, the schematic nature of roadmaps leads to the ability to view all parts of the molecule simultaneously.

To view all parts of the molecule, cylindrical projections are used that are similar to those used in atlases. This is possible because the representation is schematic (not realistic), and longitudinal distortion, similar to that near the poles in world maps, is acceptable. The surface is projected outwards radially onto a cylinder that wraps around the macromolecule (Fig. 22.2.4.3). Active-site clefts, drug or inhibitor binding sites and pores can be similarly illustrated by projecting their surfaces outward (from the axis) onto a cylinder that encloses the pore, pocket, or cleft. Such clefts are rarely straight, but with some distortion a satisfactory representation is possible by segmenting the cylinder, so that its axis follows the (curved) centre of the binding site or pore (Fig. 22.2.4.3).

22.2.5. Conclusion

Both quantitative and qualitative analyses of the surfaces of biomolecules are among the most powerful methods of elucidating functional mechanism from three-dimensional structures. A wide array of methods have been developed to help understand binding interactions and macromolecular assembly and to visualize the shape and physiochemical surface properties of macromolecules. Visualization methods range from those that depict a realistic impression of the topology to those that are more schematic and facilitate collation of structural and genetic information.

The authors thank Genfa Zhou for providing Fig. 22.2.4.1. MSC gratefully acknowledges the support of the National Science Foundation (BIR 94-18741 and DBI 98-08098), the National Institutes of Health (GM 55837) and the Markey Charitable Trust.

Chapter 22.3. Hydrogen bonding in biological macromolecules

E. N. Baker

22.3.1. Introduction

The hydrogen bond (Huggins, 1971) plays a critical role in the structure and function of biological macromolecules. This is because, uniquely among the non-covalent interactions that stabilize such structures, it combines a strong directional character with its energetic contributions. Thus, hydrogen-bonding patterns define the secondary structures that form the framework of proteins, are responsible for the specificity of base pairing in nucleic acids, shape the loops and irregular features that often determine molecular recognition, and provide for appropriately oriented functional groups in catalytic and/or binding sites.

Much of our present knowledge of hydrogen bonding in biological structures is foreshadowed in Linus Pauling's influential book (Pauling, 1960), and Jeffrey & Saenger (1991) provide a very comprehensive review. Other important reviews have covered hydrogen-bonding patterns in globular proteins (Baker & Hubbard, 1984; Stickle *et al.*, 1992), and more focused reviews address particular aspects: the satisfaction of hydrogen-bonding potential in proteins (McDonald & Thornton, 1994*a*), hydrogen-bonding patterns for side chains (Ippolito *et al.*, 1990), side-chain hydrogen bonding in relation to secondary structures (Bordo & Argos, 1994), distributions of side-chain–main-chain hydrogen bonds (Eswar & Ramakrishnan, 2000) and the hydrogen bonds associated with protein–ligand interactions (Torrance *et al.*, 2007; Liu *et al.*, 2008). The prevalence and importance of weak and non-conventional hydrogen bonds has been comprehensively reviewed by Desiraju & Steiner (1999).

22.3.2. Nature of the hydrogen bond

Hydrogen bonds have traditionally been defined as attractive electrostatic interactions of the type $D-\mathrm{H}\cdots A$, where the H atom is formally attached to a donor atom, D (assumed to be more negative than H), and is directed towards an electron-rich acceptor, A. The acceptor A is normally an electronegative atom, usually O or N, but occasionally S or Cl, with a full or partial negative charge and a lone pair of electrons directed towards the H atom. Although most of the hydrogen bonds in proteins and nucleic acids are $\mathrm{N-H\cdots O}$ or $\mathrm{O-H\cdots O}$ (less often, $\mathrm{N-H\cdots N}$), it is important to be aware that other possibilities exist, including $\mathrm{N-H\cdots S}$, $\mathrm{O-H\cdots S}$ and $\mathrm{C-H\cdots O}$, and that these can be very important in specific cases (Adman *et al.*, 1975; Derewenda *et al.*, 1995). Likewise, the π-electron clouds of aromatic rings can also act as acceptors for appropriately oriented $D-\mathrm{H}$ groups (Legon & Millen, 1987; Mitchell *et al.*, 1994). To cover this full spectrum of interactions, the formal definition of the hydrogen bond has recently been revised; see the definition in Desiraju (2011).

In an ideal hydrogen bond, the donor heavy atom, the H atom, the acceptor lone pair and the acceptor heavy atom should all lie in a straight line (Legon & Millen, 1987), as illustrated in Fig. 22.3.2.1(*a*). The strength of the interaction is also expected to depend on the electronegativities of the atoms involved. Hydrogen bonds are said to be bifurcated when a single $D-\mathrm{H}$ group interacts with two acceptors in a three-centred hydrogen bond (Fig. 22.3.2.1*b*); these hydrogen bonds are necessarily nonlinear and weaker. However, the term bifurcated is also sometimes applied to the quite different situation where a donor atom with two H atoms or an acceptor atom with two lone pairs makes two hydrogen bonds, as in Figs. 22.3.2.1(*c*) and (*d*). These interactions can be strong and linear. Some hydrogen-bonding arrangements are said to be cooperative; for example, hydrogen bonding by a peptide C═O group should enhance the polarity of the whole peptide unit and hence the acidity of the amide proton and the strength of its hydrogen bonding (Jeffrey & Saenger, 1991).

22.3.3. Hydrogen-bonding groups

22.3.3.1. *Proteins*

The hydrogen-bonding capacities of the various hydrogen-bonding groups in proteins are shown in Fig. 22.3.3.1. All, with the exception of the peptide NH and Trp side-chain NH groups, can participate in more than one hydrogen-bond interaction. Peptide and side-chain C═O groups, for example, can act as acceptors for two hydrogen bonds by using both lone pairs of electrons on the sp^2-hybridized oxygen. Likewise, the —OH groups of Ser or Thr can act as donors through their single H atom, and acceptors through their two lone pairs. In Tyr side chains, the C—O bond has some double-bond character, and the phenolic —OH is thus likely to prefer only two hydrogen bonds, both in the ring plane. The carboxylate groups of Asp and Glu are normally ionized above pH 4 and their C—O bonds also have partial double-bond character; each carboxylate oxygen should then be able to accept two hydrogen bonds, although the restriction to two may be less severe than for C═O.

Several uncertainties exist. Crystallographically, it is not usually possible to distinguish the amide oxygen and nitrogen atoms of Asn and Gln, and the decision as to which is which has to be made on environmental grounds by considering what

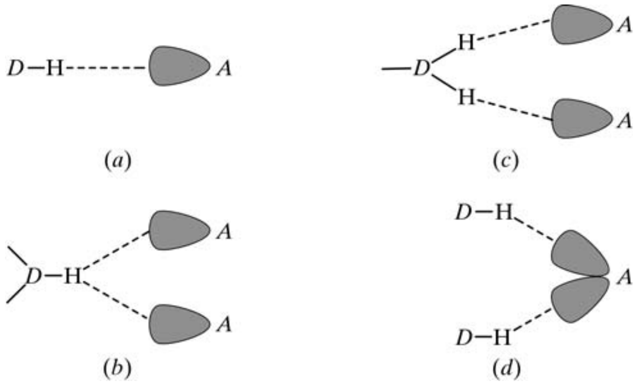

Figure 22.3.2.1
Hydrogen-bonding configurations. (*a*) The standard two-centre hydrogen bond in which an H atom attached to a donor atom, *D*, is directed towards a lone pair of an acceptor, *A*. (*b*) A classic three-centre, or bifurcated, hydrogen bond, with a single H atom shared between the lone pairs of two acceptors. The situations shown in (*c*) and (*d*) are not true three-centre hydrogen bonds since they are essentially equivalent to that in (*a*).

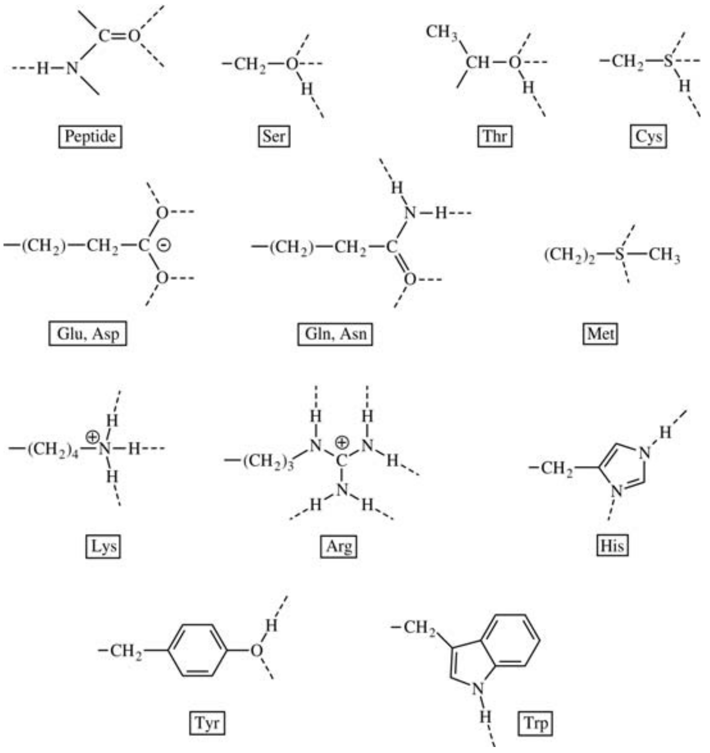

Figure 22.3.3.1
Hydrogen-bonding potential of protein functional groups. Potential hydrogen bonds are shown with broken lines. Arg, Lys, Asp and Glu side chains are shown in their ionized forms.

hydrogen bonds would be made in each of the two possible arrangements. Likewise, two possibilities exist for His side chains by rotating 180° about $C^{\beta}-C^{\gamma}$. This problem is discussed by McDonald & Thornton (1994*b*), and is addressed by their program *HBPLUS* and by validation programs such as *MolProbity* (Chapter 21.6; Richardson *et al.*, 2003).

For some side chains, the ionization state is uncertain. Arg and Lys are assumed to be fully protonated, as in Fig. 22.3.3.1, and Asp and Glu are assumed to be fully ionized. Nevertheless, several surveys of interactions in protein structures (Flocco & Mowbray, 1995; Langkilde *et al.*, 2008) show that a small but significant number of short O$\cdots$O distances between Asp and Glu side chains must represent O$-$H$\cdots$O hydrogen bonds, with one carboxyl group protonated. His side chains, in addition to the orientational uncertainty, have a pK_a (~6.5) that implies that they may be in either their neutral or their protonated form, depending on pH and environment. In the neutral form, only one N atom is protonated (more often $N^{\varepsilon 2}$, but sometimes $N^{\delta 1}$), but in the protonated form both N atoms carry protons; again, the actual state has to be deduced from their environment.

22.3.3.2. *Nucleic acids*

The three components of nucleic acids, *i.e.* phosphate groups, sugars and bases, all participate in hydrogen bonding to greater or lesser extent. The phosphate oxygen atoms can potentially act as acceptors of two or more hydrogen bonds and are frequently the recipients of hydrogen bonds from protein side chains in protein–DNA complexes. The sugar residues of RNA have a 2′-OH which can act as both hydrogen-bond donor and acceptor, and the 4′-O of both ribose and deoxyribose can potentially accept two hydrogen bonds.

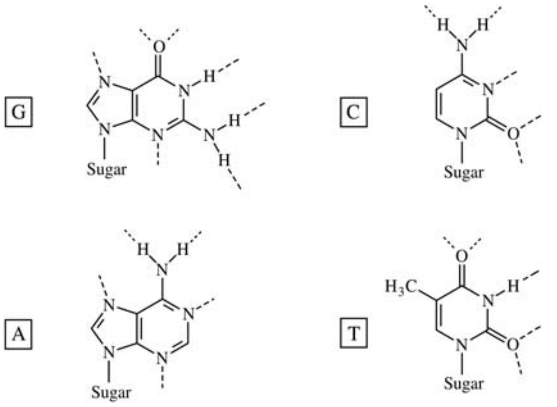

Figure 22.3.3.2
Hydrogen-bonding potential of nucleic acid bases guanine (G), adenine (A), cytosine (C) and thymine (T) in their normal canonical forms.

It is the bases of DNA and RNA that have the greatest hydrogen-bonding potential, however, with a variety of hydrogen-bond donor or acceptor sites. Although each of the bases could theoretically occur in several tautomeric forms, only the canonical forms shown in Fig. 22.3.3.2 are actually observed in nucleic acids. This leads to clearly defined hydrogen-bonding patterns which are critical to both base pairing and protein–nucleic acid recognition. The $-NH_2$ and >NH groups act only as hydrogen-bond donors, and C═O only as acceptors, whereas the >N$-$ centres are normally acceptors but at low pH can be protonated and act as hydrogen-bond donors.

22.3.4. Identification of hydrogen bonds: geometrical considerations

Because hydrogen bonds are electrostatic interactions for which the attractive energy falls off rather slowly (Hagler *et al.*, 1974), it is not possible to choose an exact cutoff for hydrogen-bonding distances. Rather, both distances and angles must be considered together; the latter are particularly important because of the directionality of hydrogen bonding. Inferences drawn from distances alone can be highly misleading. An approach with an N$-$H$\cdots$O angle of 90° and an H$\cdots$O distance of 2.5 Å would be very unfavourable for hydrogen bonding, yet it translates to a N$\cdots$O distance of 2.7 Å. This could (wrongly) be taken as evidence of a strong hydrogen bond.

For macromolecular structures determined by X-ray crystallography, problems also arise from the imprecision of atomic positions and the fact that H atoms cannot usually be seen. Thus, the geometric criteria must be relatively liberal. H atoms should also be added in calculated positions where this is possible; this can be done reliably for most NH groups (peptide NH, side chains of Trp, Asn, Gln, Arg, His, and all >NH and NH_2 groups in nucleic acid bases).

The hydrogen-bond criteria used by Baker & Hubbard (1984) are shown in Fig. 22.3.4.1. Very similar criteria are used in the program *HBPLUS* (McDonald & Thornton, 1994*a*), which also adds H atoms in their calculated positions if they are not already present in the coordinate file. In general, hydrogen bonds may be inferred if an interatomic contact obeys *all* of the following criteria:

(1) The distance H$\cdots$$A$ is less than 2.5 Å (or $D\cdots A$ less than 3.5 Å if the donor is an $-$OH or $-NH_3^+$ group or a water molecule).
(2) The angle at the H atom, $D-\mathrm{H}\cdots A$, is greater than 90°.
(3) The angle at the acceptor, $AA-A\cdots\mathrm{H}$ (or $AA-A\cdots D$ if the H-atom position is unreliable), is greater than 90°.

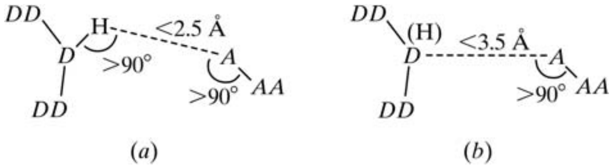

Figure 22.3.4.1
Suggested criteria for identifying likely hydrogen bonds. *DD* and *AA* represent atoms covalently bonded to the donor atom, *D*, and acceptor atom, *A*, respectively. Here, (*a*) represents the criteria when the donor H atom can be placed, and (*b*) when it cannot be placed. Additional criteria based on the angle $DD-D\cdots A$ could be incorporated with (*b*). Adapted from Baker & Hubbard (1984) and McDonald & Thornton (1994*a*).

Other criteria can be applied, for example taking into account the hybridization state of the atoms involved and the degree to which any approach lies in the plane of the lone pair(s). In all analyses of hydrogen bonding, however, it is clear that a combination of distance and angle criteria is effective in excluding unlikely hydrogen bonds.

22.3.5. Hydrogen bonding in proteins

22.3.5.1. Contribution to protein folding, stability and function

The net contribution of hydrogen bonding to protein folding and stability has been the subject of much debate over the years (Pace, 2009). The current view is that although the hydrophobic effect provides the driving force for protein folding (Kauzmann, 1959), many polar groups, notably peptide NH and C═O groups, inevitably become buried during this process, and failure of these groups to find hydrogen-bonding partners in the folded protein would be strongly destabilizing. This, therefore, favours the formation of secondary structures and other structures that permit effective hydrogen bonding in the folded molecule. Not surprisingly, the contribution of specific hydrogen bonds to stability depends on their location in the structure (Fersht & Serrano, 1993). Mutagenesis studies have shown that even the loss of a single hydrogen bond can be significantly destabilizing (Alber *et al.*, 1987) and that the energetic contribution can vary depending on whether or not the groups involved are charged (Fersht *et al.*, 1985). A recent experimental study shows that the polarity of the microenvironment of a hydrogen bond can increase its strength by up to 1.2 kcal mol^{-1} (1 kcal mol^{-1} = 4.184 kJ mol^{-1}) (Gao *et al.*, 2009).

Hydrogen bonds are fundamental to protein function, notably in the catalytic activity and specificity of enzymes (Gutteridge & Thornton, 2005). The concept of very short, low-barrier hydrogen bonds (LBHBs) that play a special role in enzyme catalysis has been proposed (Cleland *et al.*, 1998) but is controversial (Schutz & Warshel, 2004). Short, strong hydrogen bonds can be detected by NMR (see the discussion in Langkilde *et al.*, 2008) but do not stand out in crystal structures, and their functional role remains unclear.

22.3.5.2. Saturation of hydrogen-bond potential

A consistent conclusion from analyses of protein structures is that virtually all polar atoms either form explicit hydrogen bonds or are at least in contact with external water. The extent to which their *full* hydrogen-bond potential is fulfilled in a folded protein (for example, the potential of an Arg side chain to make five hydrogen bonds) has been examined in several studies. Baker & Hubbard (1984) considered the explicit hydrogen bonds made by main-chain and side-chain atoms in a number of refined protein structures and established general patterns for both, but did not differentiate buried and solvent-exposed atoms or allow for unmodelled solvent. Savage *et al.* (1993) used the solvent accessibilities of polar groups to estimate their assumed numbers of hydrogen bonds to external water. This supplemented the explicit hydrogen bonds that could be derived from the atomic coordinates and allowed an estimate of the extent to which potential hydrogen bonds are lost during protein folding. McDonald & Thornton (1994*a*) focused specifically on buried hydrogen-bond donors and acceptors in order to determine the extent to which the hydrogen-bond potential of these is utilized.

The results of these analyses can be summarized as follows. Almost all polar groups do in fact make at least one hydrogen bond. Hydrogen-bond donors are almost always hydrogen bonded; only 4% of NH groups 'lose' hydrogen bonds as a result of protein folding (Savage *et al.*, 1993). On the other hand, hydrogen-bond acceptors often do not exert their full hydrogen-bonding potential. For example, for main-chain C═O groups, which are expected to accept two hydrogen bonds, 24% of possible hydrogen bonds are estimated to be lost during folding (Savage *et al.*, 1993). Among buried C═O groups, although very few make no hydrogen bonds (as little as 2% if hydrogen-bonding criteria are relaxed), the majority fail to form a second hydrogen bond (McDonald & Thornton, 1994*a*). Steric factors, particularly in β-sheets or where Pro residues are adjacent, restrict hydrogen-bonding possibilities, although some of the 'lost' interactions may be recovered through $\mathrm{C-H\cdots O}$ interactions (see Section 22.3.7.1). McDonald & Thornton also point out that failure to form a second hydrogen bond is less energetically expensive than failure to form the first. Among polar side chains, the ionizable side chains (Asp, Glu, Arg, Lys, His) show a very strong tendency to be fully hydrogen bonded or solvent exposed. Buried Arg side chains, for example, frequently form all five possible hydrogen bonds. The side chains that most often fail to fulfil their full hydrogen-bond potential are Ser, Thr and Tyr; these almost always donate one hydrogen bond but frequently fail to accept one.

22.3.5.3. Secondary structures

Secondary structures provide the means whereby the polar C═O and NH groups of the polypeptide chain can remain effectively hydrogen bonded when they are buried within a folded globular protein. In doing so, they provide the framework of folding patterns and account for the majority of hydrogen bonds within protein structures. The three secondary-structure classes (helices, β-sheets and turns) are each characterized by specific hydrogen-bonding patterns, which can be used for objective identification of these structures (Stickle *et al.*, 1992).

22.3.5.3.1. Helices

Helices have traditionally been defined in terms of their $\mathrm{N-H\cdots O{=}C}$ hydrogen-bonding patterns as α-helices ($i \to i-4$), 3_{10}-helices ($i \to i-3$) or π-helices ($i \to i-5$); in an α-helix, for example, the peptide NH of residue 5 hydrogen bonds to the C═O of residue 1. In fact, the vast majority of helices in proteins are α-helices; 3_{10}-helices are rarely more than two turns (six residues) in length, and only a very small number of discrete, but short, π-helices have been seen so far (Weaver, 2000).

The residues within helices have characteristic main-chain torsion angles, (φ, ψ), of around (−63°, −40°) that cause the C═O groups to tilt outwards by about 14° from the helix axis (Baker & Hubbard, 1984). This results in somewhat less linear hydrogen bonding than in the original Pauling model (Pauling *et al.*, 1951), with a degree of distortion towards 3_{10}-helix geometry. Thus, weak $i \rightarrow i-3$ interactions are often made in addition to the more favourable $i \rightarrow i-4$ hydrogen bonds, giving hydrogen-bond networks that may enhance helix elasticity (Stickle *et al.*, 1992). Tilting outwards also makes the C=O groups more accessible for additional hydrogen bonds from side chains or water molecules. For the α-type, $i \rightarrow i-4$ interactions, the hydrogen-bond angles at both donor and acceptor atoms are quite tightly clustered (N—H···O ~157° and C=O···H ~147°). The hydrogen-bond lengths in helices average 2.06 (16) Å (O···H) or 2.99 (14) Å (O···N) (Baker & Hubbard, 1984).

Few helices are regular throughout their length. Many are curved or kinked such that one side (often the outer, solvent-exposed side) of the helix is opened up a bit and has longer hydrogen bonds (Blundell *et al.*, 1983; Baker & Hubbard, 1984). The bends are often associated with additional hydrogen bonds from water molecules or side chains to C=O groups that are tilted out more than usual. Curved helices are normal in coiled-coil structures and can enable long helices to pack more effectively in globular structures. Sometimes a kink can be functionally important, as in manganese superoxide dismutase, where a kink in a long helix, incorporating a π-type ($i \rightarrow i-5$) hydrogen bond, enables the optimal positioning of active-site residues (Edwards *et al.*, 1998).

The beginnings and ends of helices are sites of hydrogen-bonding variations which can be seen as characteristic 'termination motifs'. At helix N-termini, 3_{10}-type $i \rightarrow i-3$ (or bifurcated $i \rightarrow i-3$ and $i \rightarrow i-4$) hydrogen bonds are often found. At C-termini, two common patterns occur. In one, labelled α_{C1} by Baker & Hubbard (1984), there is a transition from α-type, $i \rightarrow i-4$ to 3_{10}-type, $i \rightarrow i-3$ hydrogen bonding, often with genuine bifurcated hydrogen bonds, as in Fig. 22.3.2.1(*b*), at the transition point. The other, labelled α_{C2} (Baker & Hubbard, 1984) or referred to as the 'Schellman motif' (Schellman, 1980), has a π-type, $i \rightarrow i-5$ hydrogen bond coupled with a 3_{10}-type, $i-1 \rightarrow i-4$ hydrogen bond; residue $i-1$ has a left-handed α configuration and is often Gly. The beginnings and ends of helices are also the sites of specific side-chain hydrogen-bonding patterns, referred to as N-caps and C-caps (Presta & Rose, 1988; Richardson & Richardson, 1988); these are described below.

22.3.5.3.2. *β-sheets*

β-sheets consist of short strands of polypeptide (typically 5–7 residues) running parallel or antiparallel and cross-linked by N—H···O=C hydrogen bonds. Although the (φ, ψ) angles of residues within β-sheets can be quite variable, the hydrogen-bonding patterns within these segments tend to be quite regular, as in the original Pauling models (Pauling & Corey, 1951). Occasional β-bulges in the middle of β-strands can interrupt the hydrogen-bonding pattern (Richardson *et al.*, 1978), but otherwise disruptions occur only at the ends of strands. The hydrogen bonds in β-sheets appear to be slightly shorter than those in helices, by ~0.1 Å, and also more linear (N—H···O ~ 160°, compared with ~157° in helices) (Baker & Hubbard, 1984). There also appears to be no difference between parallel and antiparallel β-sheets in the hydrogen-bond lengths and angles.

22.3.5.3.3. *Turns*

By far the most common type of turn is the β-turn, a sequence of four residues that brings about a reversal in the polypeptide chain direction. Hydrogen bonding does not seem to be essential for turn formation, but a common feature is a hydrogen bond between the C=O group of residue 1 and the NH group of residue 4, a 3_{10}-type, $i \rightarrow i-3$ interaction. Turns are also often associated with characteristic side-chain–main-chain hydrogen-bond configurations (see below). The hydrogen bonds in turns tend to be longer and less linear than those in helices and β-sheets; in particular, the angle at the acceptor oxygen atom C—O···H is around 120° (Baker & Hubbard, 1984).

In addition to β-turns, a small but significant number of γ-turns are found. In these three-residue turns, a hydrogen bond is formed between the C=O of residue 1 and the NH of residue 3, an $i \rightarrow i-2$ interaction. Although the approach to the acceptor oxygen atom is highly nonlinear (C—O···H ~ 100°), the nonlinearity at the H atom is less pronounced (N—H···O ~ 130–150°) (Baker & Hubbard, 1984). γ-turns are again of several types, depending on the configuration of the central residue. The classic γ-turn, first recognized by Matthews (1972) and Nemethy & Printz (1972), has a central residue with (φ, ψ) angles around (70°, −60°), which puts it in the normally disallowed region of the Ramachandran plot. More common, however, are structures in which an $i \rightarrow i-2$ hydrogen bond is associated with a central residue with a configuration around (90°, −70°) (Baker & Hubbard, 1984); these structures are not necessarily true turns in the sense of bringing about a sharp chain reversal, however.

22.3.5.3.4. *Aspects of in-plane geometry*

For hydrogen bonds involving sp^2 donors and/or acceptors, optimal interaction is expected to occur when the donor D—H group and the acceptor lone-pair orbital are coplanar (Taylor *et al.*, 1983). Analysis of 'in-plane' and 'out-of-plane' components of N—H···O hydrogen bonds in proteins shows that these have characteristic values for different secondary structures (Artymiuk & Blake, 1981; Baker & Hubbard, 1984). The out-of-plane component is tightly clustered at ~25° for helices and ~60° for the most common β-turns (type I and type III), but is widely scattered around a mean of 0° for β-sheets. The latter reflects different twists or curvature of β-sheets. The large out-of-plane component for turns is consistent with a relatively weak interaction.

22.3.5.4. *Side-chain hydrogen bonding*

An important concept in understanding the patterns of side-chain hydrogen bonding in proteins is that of local *versus* non-local interactions; local means that a side chain hydrogen bonds to another residue that is relatively close to it in the linear amino-acid sequence. Baker & Hubbard (1984) were first to introduce this distinction, with local defined as ±4 residues. Eswar & Ramakrishnan (2000) define local as ±5 residues, Bordo & Argos (1994) as ±6 residues and Stickle *et al.* (1992) as ±10 residues. The distinction is not important, but the distributions in all three analyses show that ±5 would encompass all the significant populations of local hydrogen bonds. Local hydrogen bonds, in which side chains interact with nearby main-chain atoms or other side chains, are evidently critical for protein folding. Non-local hydrogen bonds, although fewer in number (see below), in turn can be very important for stabilization of the folded protein.

If hydrogen bonds with water are excluded, a rule of thirds applies. Approximately one-third of the hydrogen bonds made by side chains (sch's) are with main-chain (mch) C=O groups, one-third are with main-chain NH groups, and one-third with other side chains. Within these populations, however, there are significant differences. For sch–mch(C=O) hydrogen bonds,

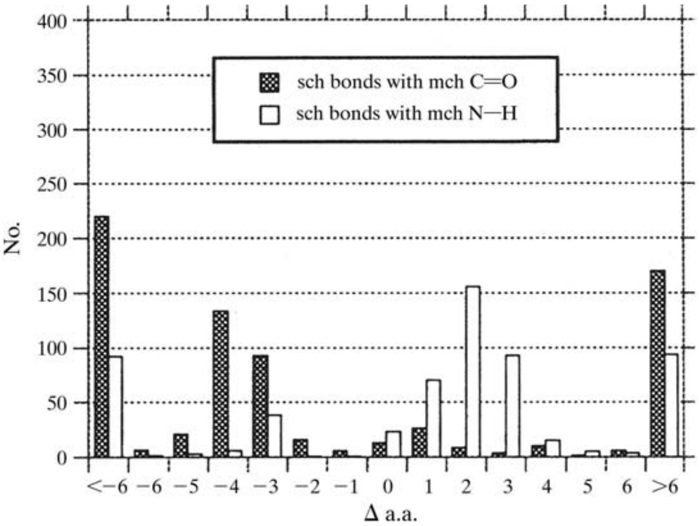

Figure 22.3.5.1
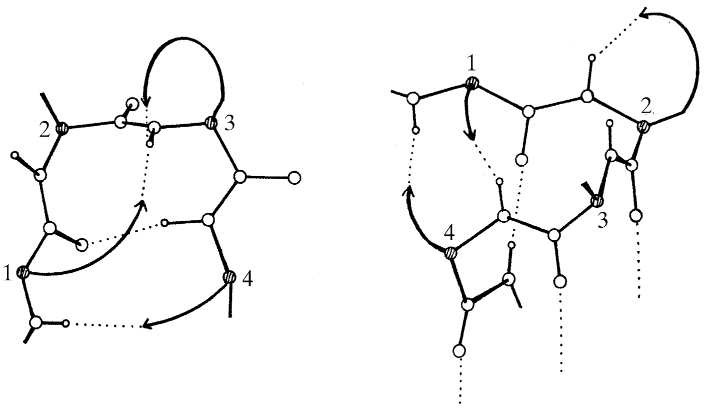
Distribution of side-chain–main-chain hydrogen bonds as a function of the separation (Δ a.a.) along the polypeptide between the side-chain (sch) and main-chain (mch) groups involved, *i.e.* Δ a.a. = −*n* means that a side chain interacts with a main-chain group *n* residues earlier in the polypeptide (towards the N-terminus). Reproduced with permission from Bordo & Argos (1994). Copyright (1994) Academic Press.

approximately 45% are local; for sch–mch(NH) hydrogen bonds, a much higher proportion is local (69%), and for sch–sch hydrogen bonds, the proportion is much less (35%) (Bordo & Argos, 1994).

The distribution of local sch–mch(NH) hydrogen bonds shows a marked positional preference (Fig. 22.3.5.1) that highlights consistent hydrogen-bonding motifs found in all proteins (Fig. 22.3.5.2). The major peak involves side chains that interact with an NH group two residues further on in the polypeptide, an *n*–NH(*n* + 2) hydrogen bond. This motif primarily involves Asp, Asn, Ser and Thr side chains and is most often found (i) in turns, where a side chain from position 1 hydrogen bonds to the NH of residue 3, (ii) in loop regions where it stabilizes the local structure but is not necessarily associated with chain reversal, and (iii) at helix N-termini.

Helix N-termini are also the site of other characteristic local side-chain–NH hydrogen-bonding motifs (Baker & Hubbard, 1984; Presta & Rose, 1988; Richardson & Richardson, 1988; Harper & Rose, 1993; Bordo & Argos, 1994). Prominent among these are sch–NH(*n* + 3) hydrogen bonds involving Ser, Thr, Asp and Asn side chains, but sch–NH(*n* − 3) interactions, in which Glu or Gln side chains hydrogen bond back to a main-chain NH, form an important lesser category. Other motifs, such as that in which a Glu or Gln side chain bends round to hydrogen bond to its own NH group, are also found. Collectively, these contribute to helix capping motifs (Fig. 22.3.5.2*b*) that help satisfy the hydrogen bonding of the 'free' NH groups of the helix N-terminus and in effect extend the helix; the sch–mch(NH) hydrogen bond mimics the mch–mch C═O···HN hydrogen bonds of the helix. Helix N-capping by side chains is probably a very important influence in protein folding, acting as a stereochemical code for helix initiation (Presta & Rose, 1988; Harper & Rose, 1993).

The distribution of sch–mch(CO) hydrogen bonds also shows a striking preference, this time for positions −3 and −4. These sch–CO(*n* − 3) or sch–CO(*n* − 4) hydrogen bonds account for the vast majority of local hydrogen bonds between side chains and main-chain C═O groups. Almost all (∼85%) are in helices, with most of the remainder in turns. They involve predominantly (∼80%) Ser and Thr side chains but other side chains (Asn, His, Arg) can also participate. These local hydrogen bonds can occur at any point along a helix, where they are often associated with helix bending or kinking (Baker & Hubbard, 1984). However, they are most frequently found at helix C-termini (Bordo & Argos, 1994) and may constitute a termination motif.



(*a*) (*b*)

Figure 22.3.5.2
Schematic representations of common classes of side-chain–main-chain hydrogen bonds (*a*) in turns and (*b*) at helix N-termini. Arrows represent side chains that hydrogen bond to main-chain CO or NH groups (NH identified by the small circle for H).

Local side-chain–side-chain hydrogen bonds, although common, do not seem to fit into any obvious patterns; the only recurring interaction identified so far is between side chains on succeeding turns of helices, *i.e.* separated by approximately four residues. These frequently involve charged side chains, which can form hydrogen-bonded ion pairs. In sections of extended chain, side chains that are two residues apart may similarly interact.

Non-local hydrogen bonding by side chains is less easy to categorize but is no less significant; more than 50% of side-chain–main-chain(C═O) hydrogen bonds are non-local, as are ∼65% of side-chain–side-chain hydrogen bonds. In most proteins, a small number of polar side chains with multiple hydrogen-bonding capability act as the centre for networks of hydrogen bonds; these appear to be particularly important for stabilizing non-repetitive polypeptide chain structures (coil, loops). Examples are given in Baker & Hubbard (1984). Most often these involve larger side chains with more than one hydrogen-bonding centre (Asn, Asp, Gln, Glu, Arg, His) which cross-link different sections of the polypeptide. Arg side chains interacting with main-chain C═O groups seem to be particularly effective; Ser and Thr, on the other hand, are seldom used, even though both have the potential to form three hydrogen bonds.

The geometry of side-chain hydrogen bonding has been analysed by Baker & Hubbard (1984) and, more extensively, by Ippolito *et al.* (1990). The former concentrate on hydrogen-bond lengths and angles and show that the preferred angles fit well with stereochemical expectations. Ippolito *et al.* examine the preferences for the various hydrogen-bonding sites around each side-chain type by means of scatter plots (Fig. 22.3.5.3) from which probability densities are computed. These show that well defined preferences exist, determined by both steric and electronic effects.

22.3.5.5. *Hydrogen bonds with water molecules*

Water molecules, with their small size and double-donor, double-acceptor hydrogen-bonding capability, are ideal for completing intramolecular hydrogen-bonding networks, *e.g.* by linking two proton acceptor atoms, or two protein donor atoms, that cannot otherwise interact. Thus, buried water molecules, making multiple hydrogen bonds, help satisfy the hydrogen-bond potential of internal polar atoms and contribute to protein stability; internal waters average about three hydrogen bonds each (Baker & Hubbard, 1984; Williams *et al.*, 1994). From the survey of Williams *et al.* (1994), most (58%) occupy discrete cavities, while 22% are in clusters housing two waters and 20% are in larger clusters; some examples of larger clusters are given in Baker & Hubbard (1984). Buried waters are often conserved between homologous proteins (Baker, 1995), and each buried water–protein hydrogen bond is estimated to stabilize a folded protein by, on average, 0.6 kcal mol^{-1} (Williams *et al.*, 1994). More loosely bound external waters exchange much more rapidly and presumably contribute less energetically.

Several patterns of hydrogen bonding are consistently observed. Water molecules are most often seen interacting with oxygen atoms rather than nitrogen atoms and acting as hydrogen-bond donors rather than acceptors. Possible reasons include the greater number of acceptor sites in proteins and the fewer geometrical restrictions imposed by acceptors (Baker & Hubbard, 1984; Baker, 1995). There is also a predominance of interactions with main-chain atoms rather than side-chain atoms: on average ~40% with main-chain C=O groups, 15% with main-chain NH and 45% with side-chain groups (Baker & Hubbard, 1984; Thanki *et al.*, 1988). Favoured main-chain binding sites include the N- and C-termini of helices, C=O groups on the solvent-exposed sides of helices, the edge strands of β-sheets, and the ends of strands where they add extra inter-strand hydrogen bonds at the position where the strands diverge (Thanki *et al.*, 1991). Among side chains, the most highly hydrated appear to be Asp and Glu, whose COO$^-$ groups bind, on average, two water molecules each (Baker & Hubbard, 1984; Thanki *et al.*, 1988). On the other hand, the best-ordered water sites are created by residues whose side chains simultaneously make hydrogen bonds to other protein atoms (His, Asp, Asn, Arg) or may be sterically restricted (Tyr, Trp).

The distributions of water molecules around protein groups follow the geometrical patterns expected from simple bonding ideas (Baker & Hubbard, 1984; Thanki *et al.*, 1988). Interactions with NH groups are linear, and those with C=O groups show a preferred angle of ~130° at the oxygen-atom acceptor, consistent with interaction with an oxygen-atom lone pair; restriction to the peptide plane is not very strong, however. Although the distributions around polar side chains generally follow the expected patterns (Thanki *et al.*, 1988), there is little evidence of ordered water clusters around non-polar groups. This may be because water clusters need to be 'anchored' by hydrogen bonding to polar groups to be seen crystallographically.

22.3.6. Hydrogen bonding in nucleic acids

Hydrogen bonding by purine and pyrimidine bases is, together with base stacking, a major determinant of nucleic acid structure. With so many hydrogen-bonding groups, there are many potential modes of interaction between bases (Jeffrey & Saenger, 1991). Those that are actually found in DNA and RNA structures are, however, much more restricted in number, at least based on presently available experimental data.

22.3.6.1. DNA

DNA structure is dominated by the prevalence of duplex structures and hence by the classic Watson–Crick hydrogen-bonding pattern of A–T and G–C base pairs. This hydrogen-bonding pattern is not affected by whether the double helix has A-form, B-form or Z-form geometry. Other hydrogen-bonding modes in DNA are probably very rare, arising only as a result of mutations (which produce mismatches), chemical modifications, such as methylation, or other disturbances, such as the binding of drugs or proteins so as to alter DNA conformation. Mismatches can give stable hydrogen bonding but at the expense of local perturbations of the DNA structure.

22.3.6.2. RNA

In contrast to DNA, RNA molecules generally form single-stranded structures, which are correspondingly much more complex and less regular. This means that catalytic and other activities can be generated in addition to their information-carrying roles. Current knowledge of detailed RNA three-dimensional structure is limited to transfer RNAs and several ribozymes, including a large ribosomal RNA domain (Cate *et al.*, 1996). Even from this small sample, however, it is clear that a great diversity of hydrogen-bonding interactions exists; RNA molecules contain regions of double-helical structure, often with classical Watson–Crick A–U and G–C base pairing, but these regions are interspersed with loops and bulges and tertiary interactions between the various secondary-structural (double-helical) elements. These interactions include many unconventional base pairings (*e.g.* see Fig. 22.3.6.1).

Some RNA structural motifs may prove to be of widespread general importance in RNA molecules. One example is a sharp turn with sequence CUGA in the hammerhead ribozyme that exactly matches turns in tRNAs (Pley *et al.*, 1994). Another is the

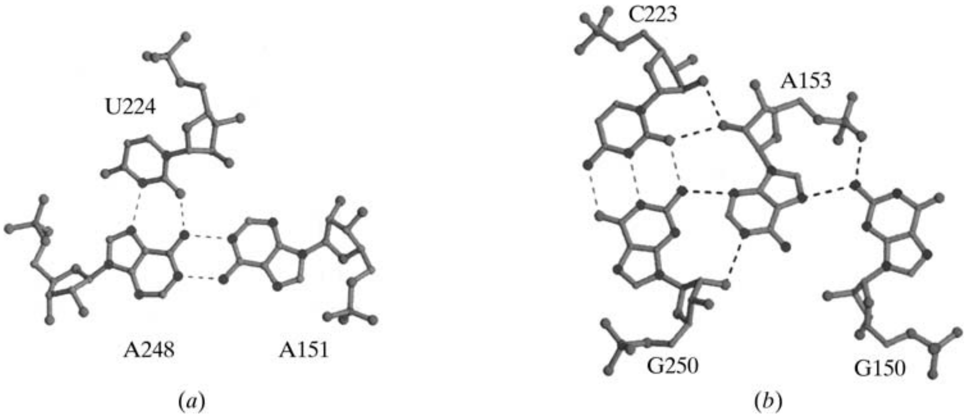

Figure 22.3.6.1
Hydrogen-bonding interactions in RNA tertiary structure. In (*a*), a triple base interaction is shown. In (*b*), G150 and A153 of a GAAA tetraloop participate in multiple hydrogen-bond interactions involving bases, riboses and phosphate. Reprinted with permission from Cate *et al.* (1996). GNRA tetraloop structure (N = any base, R = purine). This loop has a well defined structure, stabilized by hydrogen bonding and stacking involving its own bases, and it also presents further hydrogen-bonding groups that can dock into 'receptor' structures in other parts of the RNA molecule. This results in triple or quadruple base interactions (Fig. 22.3.6.1) that tie different parts of the RNA structure together; the parallel with hydrogen-bonding side chains in proteins is very strong. The 2′-hydroxyls of ribose groups are also used in some of these interactions (Fig. 22.3.6.1). Further ribose interactions involve interdigitated ribose groups that line the interfaces between adjacent helices such that pairs of riboses interact by hydrogen bonding through their 2′-hydroxyl groups, forming 'ribose zippers'. As many more RNA structures are determined experimentally, it is likely that more hydrogen-bonding motifs will be recognized, and their full role in RNA structure can be better assessed than at our present, imperfect state of knowledge.

22.3.7. Non-conventional hydrogen bonds

The vast majority of hydrogen bonds in biological macromolecules involve nitrogen and oxygen donors exclusively. Nevertheless, several other interactions have all the characteristics of hydrogen bonds and clearly contribute to structure and stability where they occur.

22.3.7.1. *C—H···O hydrogen bonds*

Sutor (1962) first summarized evidence for C—H···O hydrogen bonds following earlier suggestions by Pauling (1960), and current evidence has been nicely summarized in several articles (Derewenda *et al.*, 1995; Wahl & Sundaralingam, 1997; Jiang & Lai, 2002). The energy of C—H···O hydrogen bonds has been generally estimated as ~0.5 kcal mol^{-1} (about 10% of an N—H···O interaction) but may be higher, especially in hydrophobic environments. It also depends on the acidity of the C—H proton, with methylene (CH_2) and methyne (CH) groups being most favourable.

A number of examples of C—H···O hydrogen bonds can be found in nucleic acid structures (Wahl & Sundaralingam, 1997). The best known is that between the backbone O5′ oxygen and a purine C(8)—H or pyrimidine C(6)—H, when the bases are in the *anti* conformation. Another example is given by a U–U base pair, in which the two bases form a conventional N(3)—H···O(4) hydrogen bond and a C(5)—H···O hydrogen bond.

In proteins, two groups are regarded as being particularly significant (Derewenda *et al.*, 1995). These are the C^{ε}H of His side chains and the methylene H atoms of the main-chain α-carbon atoms. C—H···O hydrogen bonds involving His side chains have been found for the active-site His residues of proteins of the lipase/esterase family and in other proteins (Derewenda *et al.*, 1994). The C^{α}H atoms, however, appear to provide much more widespread C—H···O hydrogen bonding, especially in β-sheets, where they are directed towards the 'free' lone pairs of the main-chain C=O groups. C—H···O hydrogen bonds may thus play a previously unrecognized role in satisfying the hydrogen-bond potential of C=O groups. In general, Derewenda *et al.* (1995) find a significant number of C···O contacts that meet the criteria for C—H···O hydrogen bonds; the H···O distance peaks at 2.45 Å (C···O 3.5 Å), which is less than the van der Waals distance of 2.7 Å, and the angles indicate that the H atoms are directed at the acceptor lone-pair orbitals. C—H···O hydrogen bonds are also found in some cases to complete the tetrahedral coordination of internal water molecules (Desiraju & Steiner, 1999).

22.3.7.2. *Hydrogen bonds involving sulfur atoms*

Sulfur atoms are larger and have a more diffuse electron cloud than oxygen or nitrogen, but are nevertheless capable of participating in hydrogen bonds. Given that the radius of sulfur is ~0.4 Å greater than that of oxygen, hydrogen bonds can be assumed if the distance H···S is less than ~2.9 Å, or S···O(N) is less than ~3.9 Å, providing the angular geometry is right. In proteins, the SH group of cysteine can be a hydrogen-bond acceptor or donor, whereas the sulfur atoms in disulfide bonds and in Met side chains can act only as acceptors.

The clearest example of hydrogen bonding involving Cys residues is given by the NH···S hydrogen bonds first described in Fe-S proteins (Adman *et al.*, 1975); here, peptide NH groups are oriented to point directly at the S atoms of metal-bound Cys residues, with H···S distances of 2.4–2.9 Å. Similar NH···S hydrogen bonds are found in blue copper proteins, involving the Cys ligands. In these cases, the cysteine sulfur is deprotonated and therefore more negative, making it a stronger hydrogen-bond acceptor, and it is likely that hydrogen bonding to cysteine S^- atoms is common. A large survey of Cys and Met side chains in proteins has given evidence of both N—H···S and S—H···O hydrogen bonds involving the SH groups of Cys side chains (Gregoret *et al.*, 1991). In particular, Cys residues in helices frequently hydrogen bond to the main-chain C=O group four residues back in the helix in SH(n) ··· O($n-4$) interactions analogous to those seen for Ser and Thr residues in helices. On the other hand, O—H···S or N—H···S hydrogen bonds to the S atoms of Met or half-cystine side chains, although they do exist, are rare (Gregoret *et al.*, 1991; Ippolito *et al.*, 1990).

22.3.7.3. Amino–aromatic hydrogen bonding

Surveys of protein structures have shown that aromatic rings (of Trp, Tyr or Phe) are frequently in close association with side-chain NH groups of Lys, Arg, Asn, Gln or His (Burley & Petsko, 1986). Energy calculations further suggest that where an N—H group, as donor, is directed towards the centre of an aromatic ring, as acceptor, a hydrogen-bonded interaction with an energy of ~3 kcal mol^{-1} (about half that of a normal N—H···O or O—H···O hydrogen bond) can result (Levitt & Perutz, 1988). Whether the close associations observed by Burley & Petsko can truly be regarded as hydrogen bonds has been controversial, however. Mitchell *et al.* (1994) have analysed amino–aromatic interactions and shown that by far the most common form of association between sp^2 nitrogen atoms and aromatic rings involves approximately plane-to-plane stacking, which cannot represent hydrogen bonding. There are still, however, a significant number of cases where the H atoms of N—H groups are directed towards aromatic rings, and these represent genuine hydrogen bonds (Mitchell *et al.*, 1994). It is clearly essential to consider the donor–acceptor geometry, both distances and angles, before assuming an amino–aromatic hydrogen bond; the N···ring distance should be less than ~3.8 Å, and N—H··· C angle greater than 120°, where C is the ring centre (Mitchell *et al.*, 1994).

The author gratefully acknowledges many useful discussions with Guy Dodson and Rod Hubbard (University of York), and many other colleagues. Clyde Smith is thanked for help with figures, and research support from the Health Research Council of New Zealand and the Tertiary Education Commission of New Zealand through its support of the Maurice Wilkins Centre for Molecular Biodiscovery is acknowledged.

Chapter 22.4. Electrostatic interactions in proteins

K. A. Sharp

22.4.1. Introduction

Electrostatic interactions play a key role in determining the structure, stability, binding affinity, chemical properties, and hence the biological reactivity, of proteins and nucleic acids. Interactions where electrostatics play an important role include:

(1) Ligand/substrate association. Long-range electrostatic forces can considerably enhance association rates by facilitating translational and rotational diffusion or by reduction in the dimensionality of the diffusion space.

(2) Binding affinity. Tight specific binding is often a prerequisite for biological activity, and electrostatics make important contributions to desolvation and formation of chemically complementary interactions during binding.

(3) Modification of chemical and physical properties of functional groups such as cofactors (haems, metal ions *etc.*), alteration of the ionization energy pK_a of side chains and shifting of redox midpoints.

(4) The creation of potentials or fields in the active sites to stabilize functionally important charged or dipolar intermediates in processes such as catalysis.

In this chapter I will discuss, within the framework of classical electrostatics, how such effects can be modelled starting from the structural information provided by X-ray crystallography. Nevertheless, many of the concepts of classical electrostatics can be used in combination with molecular dynamics (MD), quantum mechanics (QM) and other computational methods to study a wider range of macromolecular properties, for example specific protein motions, the breaking or forming of bonds, determination of intrinsic pK_a's, determination of electronic energy levels *etc.*

The central aim in studying the electrostatic properties of macromolecules is to take the structural information provided by crystallography (typically the atomic coordinates, although *B*-factor information may also be of use) and obtain a realistic description of the electrostatic potential distribution $\varphi(\mathbf{r})$. The electrostatic potential distribution can then be used in a variety of ways: (i) graphical analysis may reveal deeper aspects of the structure and help identify functionally important regions or active sites; (ii) the potentials may be used to calculate energies and forces, which can then be used to calculate equilibrium or kinetic properties; and (iii) the electrostatic potentials may be used in conjunction with other computational methods such as QM and MD.

Three problems must be solved to obtain the electrostatic potential distribution. The first is to model the macromolecular charge distribution, usually by specifying the location and charge of all its atoms. Although the coordinates of the molecule are determined by crystallographic methods, the charge distribution is not. A number of atomic charge distributions have been developed for proteins and nucleic acids using quantum mechanical methods and/or parameterization to different experimental data. The second problem is that the positions of the water molecules and solvent ions are generally not known. (Water molecules and ions seen in even the best crystal structures usually constitute a small fraction of the total important in solvating the molecule. Moreover, the orientation of the crystallographic water molecules, crucial in determining the electrostatic potential, is rarely known.) Within the framework of classical electrostatics, inclusion of the *effect* of the solvating water molecules and ions is handled not by treating them explicitly, but implicitly in terms of an 'electrostatic response' to the field created by the molecular charge distribution. The third problem is that incorporation of the available structural information at atomic resolution results in a complicated spatial distribution of charge, dielectric response *etc.* Numerical methods for rapidly and accurately solving the electrostatic equations that determine the potential are therefore essential.

22.4.2. Theory

22.4.2.1. The response of the system to electrostatic fields

The response to the electrostatic field arising from the molecular charge distribution arises from three physical processes: electronic polarization, reorientation of permanent dipolar groups and redistribution of mobile ions in the solvent. Movement of ionized side chains, if significant, is sometimes viewed as part of the dielectric response of the protein, and sometimes explicitly as a conformational change of the molecule.

Electronic polarizability can be represented either by point inducible dipoles (Warshel & Åqvist, 1991) or by a dielectric constant. The latter approach relates the electrostatic polarization, $\mathbf{P}(\mathbf{r})$ (the mean dipole moment induced in some small volume V) to the Maxwell (total) field, $\mathbf{E}(\mathbf{r})$, and the local dielectric constant representing the response of that volume, $\varepsilon(\mathbf{r})$, according to

$$\mathbf{P}(\mathbf{r}) = [\varepsilon(\mathbf{r}) - 1]\mathbf{E}(\mathbf{r})/4\pi. \qquad (22.4.2.1)$$

The contribution of electronic polarizability to the dielectric constant of most organic material and water is fairly similar. It can be evaluated by high-frequency dielectric measurements or the refractive index, and it is in the range 2–2.5.

The reorientation of groups such as the peptide bond or surrounding water molecules which have large permanent dipoles is an important part of the overall response. This response too may be treated using a dielectric constant, *i.e.* using equation (22.4.2.1) with a larger value of the dielectric constant that incorporates the additional polarization from dipole reorientation. An alternative approach to equation (22.4.2.1) for treating the dipole reorientation contribution of water surrounding the macromolecules is the Langevin dipole model (Lee *et al.*, 1993; Warshel & Åqvist, 1991; Warshel & Russell, 1984). Four factors determine the degree of response from permanent dipoles: (i) the dipole-moment magnitude; (ii) the density of such groups in the protein or solvent; (iii) the freedom of such groups to reorient; and (iv) the degree of cooperativity between dipole motions. Thus, water has a high dielectric constant (ε = 78.6 at 25 °C). For electrostatic models based on dielectric theory, the experimental solvent dielectric constant, reflecting the contribution of electronic polarizability and dipole reorientation, is usually used. From consideration of the four factors that determine the

Copyright © 2012 International Union of Crystallography

dielectric response, macromolecules would be expected to have a much lower dielectric constant than the solvent. Indeed, theoretical studies of the dielectric behaviour of amorphous protein solids (Gilson & Honig, 1986; Nakamura *et al.*, 1988) and the interior of proteins in solution (Simonson & Brooks, 1996; Simonson & Perahia, 1995; Smith *et al.*, 1993), and experimental measurements (Takashima & Schwan, 1965) provide an estimate of $\varepsilon = 2.5$–4 for the contribution of dipolar groups to the protein dielectric.

The Langevin model can account for the saturation of the response at high fields that occurs if the dipoles become highly aligned with the field. The dielectric model can also be extended to incorporate saturation effects (Warwicker, 1994), although there is a compensating effect of electrostriction, which increases the local dipole density (Jayaram, Fine *et al.*, 1989). While the importance of saturation effects would vary from case to case, linear solvent dielectric models have proven sufficiently accurate for most protein applications to date.

Charge groups on molecules will attract solvent counter-ions and repel co-ions. The most common way of treating this charge rearrangement is *via* the Boltzmann model, where the net charge density of mobile ions is given by

$$\rho^m(\mathbf{r}) = \sum_i z_i e c_i^o \exp[-z_i e \varphi(\mathbf{r})/kT], \qquad (22.4.2.2)$$

where c_i^o is the bulk concentration of an ion of type i, valence z_i, and $\varphi(\mathbf{r})$ is the average potential (an approximation to the potential of mean force) at position $\mathbf{r}$. The Boltzmann approach neglects the effect of ion size and correlations between ion positions. Other models for the mobile-ion behaviour that account for these effects are integral equation models and MC models (Bacquet & Rossky, 1984; Murthy *et al.*, 1985; Olmsted *et al.*, 1989, 1991; Record *et al.*, 1990). These studies show that ion size and correlation effects do not compromise the Boltzmann model significantly for monovalent (1–1) salts at mid-range concentrations 0.001–0.5 *M*, and consequently it is widely used for modelling salt effects in proteins and nucleic acids.

22.4.2.2. Dependence of the potential on the charge distribution

The potential at a point in space, $\mathbf{r}$, arising from some charge density distribution $\rho(\mathbf{s})$ and some dipole density distribution $\mathbf{P}(\mathbf{s})$ (which includes polarization) is given by

$$\varphi(\mathbf{r}) = \int \rho(\mathbf{s})/(|\mathbf{s}-\mathbf{r}|) + \mathbf{P}(\mathbf{s})(\mathbf{s}-\mathbf{r})/(|\mathbf{s}-\mathbf{r}|^3)\,\mathrm{d}\mathbf{s}. \qquad (22.4.2.3)$$

The total charge distribution is the sum of the explicit charge distribution on the molecule and that from the mobile solvent ion distribution, $\rho = \rho^e + \rho^m$. Substituting for the dielectric polarization using equation (22.4.2.1) and for the mobile ion charge distribution using equation (22.4.2.2), the potential may be expressed in terms of a partial differential equation, the Poisson–Boltzmann (PB) equation:

$$\nabla\varepsilon(\mathbf{r})\nabla\varphi(\mathbf{r}) + 4\pi\sum_i z_i e c_i^o \exp[-z_i e\varphi(\mathbf{r})/kT] + 4\pi\rho^e(\mathbf{r}) = 0, \qquad (22.4.2.4)$$

which relates the potential, molecular charge and dielectric distributions, $\varphi(\mathbf{r})$, $\rho^e(\mathbf{r})$ and $\varepsilon(\mathbf{r})$, respectively. Contributions to the polarizability from electrons, a molecule's permanent dipoles and solvent dipoles are incorporated into this model by using an appropriate value for the dielectric for each region of protein and solvent. Values for protein atomic charges, radii and dielectric constants suitable for use with the Poisson–Boltzmann equation are available in the literature (Jean-Charles *et al.*, 1990; Mohan *et al.*, 1992; Simonson & Brünger, 1994; Sitkoff *et al.*, 1994). For protein applications, the Boltzmann term in equation (22.4.2.4) is usually linearized to become $-8\pi\varphi(\mathbf{r})I/kT$ where I is the ionic strength, whereas for nucleic acids and molecules of similarly high charge density the full nonlinear equation is used.

22.4.2.3. The concepts of screening, reaction potentials, solvation, dielectric, polarity and polarizability

Application of a classical electrostatic view to macromolecular electrostatics involves a number of useful concepts that describe the physical behaviour. It should first be recognized that the potential at a particular charged atom i includes three physically distinct contributions. The first is the direct or Coulombic potential of j at i. The second is the potential at i generated by the polarization (of a molecule, water and ion atmosphere) induced by j. This is often referred to as the screening potential, since it opposes the direct Coulombic potential. The third arises from the polarization induced by i itself. This is often referred to as the reaction or self-potential, or if solvent is involved, as the solvation potential.

When using models that apply the concept of a dielectric constant (a measure of polarizability) to a macromolecule, it is important to distinguish between polarity and polarizability. Briefly, polarity may be thought of as describing the density of charged and dipolar groups in a particular region. Polarizability, by contrast, refers to the *potential* for reorganizing charges, orienting dipoles and inducing dipoles. Thus polarizability depends both on the polarity and the freedom of dipoles to reorganize in response to an applied electric field. When a protein is folding or undergoing a large conformational rearrangement, the peptide groups may be quite free to reorient. In the folded protein, these may become spatially organized so as to stabilize another charge or dipole, creating a region with high polarity, but with low polarizability, since there is much less ability to reorient the dipolar groups in response to a new charge or dipole without significant disruption of the structure. Thus, while there is still some discussion about the value and applicability of a protein dielectric constant, it is generally agreed that the interior of a macromolecule is a less polarizable environment compared to solvent. This difference in polarizability has a significant effect on the potential distribution.

Formally charged groups on proteins, particularly the longer side chains on the surface of proteins, Arg, Lys, and to a lesser extent Glu and Asp, have the ability to alter their conformation in response to electrostatic fields. In addition, information about fluctuations about their mean position may need to be included in calculating average properties. Three approaches to modelling protein formal charge movements can be taken. The first is to treat the motions within the dielectric response. In this approach, the protein may be viewed as having a dielectric higher than 2.5–4 in the regions of these charged groups, particularly at the surface, where the concentration and mobility of these groups may give an effective dielectric of 20 or more (Antosiewicz *et al.*, 1994; Simonson & Perahia, 1995; Smith *et al.*, 1993). A second approach is to model the effect of charge motions on the electrostatic quantity of interest explicitly, *e.g.* with MD simulations (Langsetmo *et al.*, 1991; Wendoloski & Matthew, 1989). This involves generating an ensemble of structures with different atomic charge distributions. The third approach is based on the fact that one is often interested in a specific biological process $A \rightarrow B$ in which one can evaluate the structure of the protein in states A and B (experimentally or by modelling), and any change in average charge positions is incorporated at the level of different average explicit charge distribution inputs for the calculation, modelling only the electronic, dipolar and salt contributions as the response.

The term 'effective' dielectric constant is sometimes used in the literature to describe the strength of interaction between two charges, q_1 and q_2. This is defined as the ratio of the observed or calculated interaction strength, U, to that expected between the same two charges in a vacuum:

$$\varepsilon^{\rm eff} = [(q_1 q_2)/r_{12}]/U, \qquad (22.4.2.5)$$

where r_{12} is the distance between the charges. If the system were completely homogeneous in terms of its electrostatic response and involved no charge rearrangement then $\varepsilon^{\rm eff}$ would describe the dielectric constant of the medium containing the charges. This is generally never the case: the strength of interaction in a protein system is determined by the net contribution from protein, solvent and ions, so $\varepsilon^{\rm eff}$ does not give information about the dielectric property of any particular region of space. In fact, in the same system different charge–charge interactions will generally yield different values of $\varepsilon^{\rm eff}$. Thus $\varepsilon^{\rm eff}$ is really no more than its definition – a measure of the strength of interaction – and it cannot be used directly to answer questions about the protein dielectric constant, for example. Rather, it is one of the quantities that one aims to extract from theoretical models to compare with an experiment.

22.4.2.4. Calculation of energies and forces

Once the electrostatic potential distribution has been obtained, calculation of experimental properties usually requires evaluation of the electrostatic energy or force. For a linear system (where the dielectric and ionic responses are linear) the electrostatic free energy is given by

$$\Delta G^{\rm el} = 1/2 \sum_i \varphi_i q_i, \qquad (22.4.2.6)$$

where $\varphi_{\rm i}$ is the potential at an atom with charge q_i. The most common source of nonlinearity is the Boltzmann term in the PB equation (22.4.2.4) for highly charged molecules such as nucleic acids. The total electrostatic energy in this case is (Reiner & Radke, 1990; Sharp & Honig, 1990; Zhou, 1994)

$$\Delta G^{\rm el} = \int_V \{\rho^e \varphi - (\varepsilon E^2/8\pi) - kT \sum_i c_i^0 [\exp(-z_i e\varphi/kT) - 1]\}\, {\rm d}\mathbf{r}, \qquad (22.4.2.7)$$

where the integration is now over all space.

The general expression for the electrostatic force on a charge q is given by the gradient of the total free energy with respect to that charge's position,

$$\mathbf{f}_q = -\nabla_{\mathbf{r}q}(G^{\rm el}). \qquad (22.4.2.8)$$

If the movement of that charge does not affect the potential distribution due to the other charges and dipoles, then equation (22.4.2.8) can be evaluated using the 'test charge' approach, in which case the force depends only on the gradient of the potential or the field at the charge:

$$\mathbf{f} = q\mathbf{E}. \qquad (22.4.2.9)$$

However, in a system like a macromolecule in water, which has a non-homogeneous dielectric, forces arise between a charge and any dielectric boundary due to image charge (reaction potential) effects. A similar effect to the 'dielectric pressure' force arises from solvent-ion pressure at the solute–solvent boundary. This results in a force acting to increase the solvent exposure of charged and polar atoms. An expression for the force that includes these effects has been derived within the PB model (Gilson *et al.*, 1993):

$$\mathbf{f} = \rho^e \mathbf{E} - (1/2)E^2 \nabla\varepsilon - kT \sum_i c_i^0 [\exp(-z_i e\varphi/kT) - 1]\nabla A, \qquad (22.4.2.10)$$

where A is a function describing the accessibility to solvent ions, which is 0 inside the protein, and 1 in the solvent, and whose gradient is nonzero only at the solute–solvent surface. Similarly, in a two-dielectric model (solvent plus molecule) the gradient of ε is nonzero only at the molecular surface. The first term accounts for the force acting on a charge due to a field, as in equation (22.4.2.9), while the second and third terms account for the dielectric surface pressure and ionic atmosphere pressure terms respectively. Equation (22.4.2.10) has been used to combine the PB equation and molecular mechanics (Gilson *et al.*, 1995).

22.4.2.5. Numerical methods

A variety of numerical methods exist for calculating electrostatic potentials of macromolecules. These include numerical solution of self-consistent field electrostatic equations, which has been used in conjunction with the protein dipole–Langevin dipole method (Lee *et al.*, 1993). Numerical solution of the Poisson–Boltzmann equation requires the solution of a three-dimensional partial differential equation, which can be nonlinear. Many numerical techniques, some developed in engineering fields to solve differential equations, have been applied to the PB equation. These include finite-difference methods (Bruccoleri *et al.*, 1996; Gilson *et al.*, 1988; Nicholls & Honig, 1991; Warwicker & Watson, 1982), finite-element methods (Rashin, 1990; Yoon & Lenhoff, 1992; Zauhar & Morgan, 1985), multigridding (Holst & Saied, 1993; Oberoi & Allewell, 1993), conjugate-gradient methods (Davis & McCammon, 1989) and fast multipole methods (Bharadwaj *et al.*, 1994; Davis, 1994). Methods for treating the nonlinear PB equation include under-relaxation (Jayaram, Sharp & Honig, 1989) and powerful inexact Newton methods (Holst *et al.*, 1994). The nonlinear PB equation can also be solved *via* a self-consistent field approach, in which one calculates the potential using equation (22.4.2.5), then the mobile charge density is calculated using equation (22.4.2.3), and the procedure is repeated until convergence is reached (Pack & Klein, 1984; Pack *et al.*, 1986). The method allows one to include more elaborate models for the ion distribution, for example incorporating the finite size of the ions (Pack *et al.*, 1993). Approximate methods based on spherical approximations (Born-type models) have also been used (Schaeffer & Frommel, 1990; Still *et al.*, 1990). Considerable numerical progress has been made in finite methods, and accurate rapid algorithms are available. The reader is referred to the original references for numerical details.

22.4.3. Applications

An exhaustive list of applications of classical electrostatic modelling to macromolecules is beyond the scope of this chapter. Three general areas of application are discussed.

22.4.3.1. Electrostatic potential distributions

Graphical analysis of electrostatic potential distributions often reveals features about the structure that complement analysis of the atomic coordinates. For example, Fig. 22.4.3.1(*a*) shows the

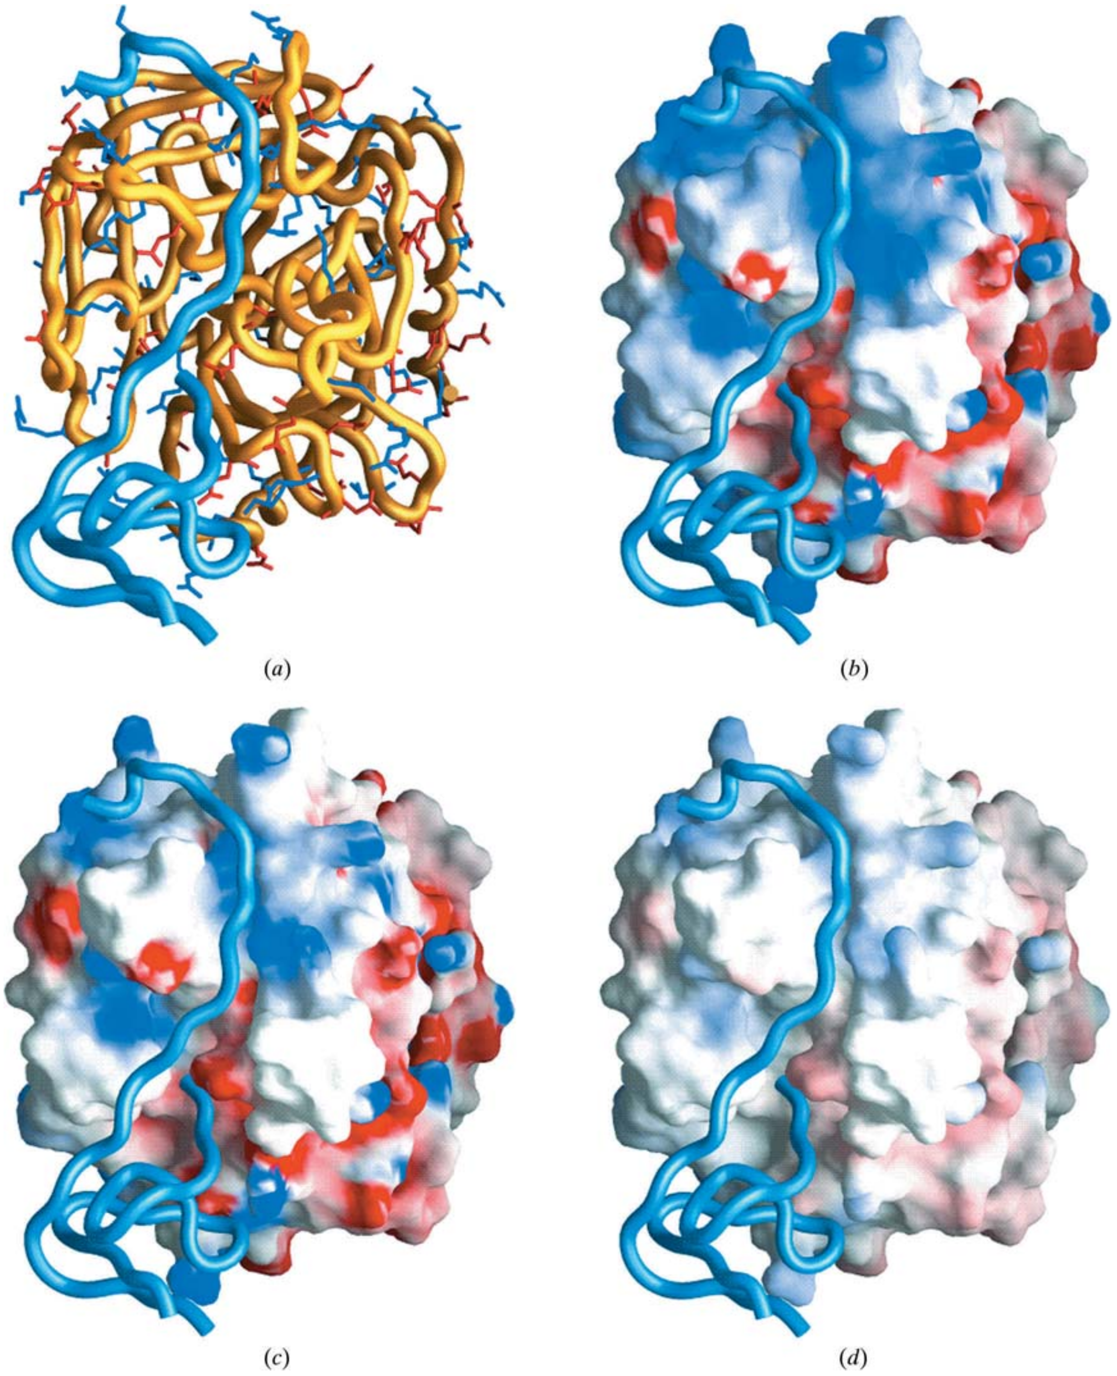

Figure 22.4.3.1
(*a*) The proteolytic enzyme thrombin (yellow backbone worm) complexed with an inhibitor, hirudin (blue backbone worm). The negatively charged (red) and positively charged (blue) side chains of thrombin are shown in bond representation. (*b*) Solvent-accessible surface of thrombin coded by electrostatic potential (blue: positive, red: negative). Hirudin is shown as a blue backbone worm. Potential is calculated at zero ionic strength. (*c*) Solvent-accessible surface of thrombin coded by electrostatic potential (blue: positive, red: negative). Hirudin is shown as a blue backbone worm. Potential is calculated at physiological ionic strength (0.145 *M*). (*d*) Solvent-accessible surface of thrombin coded by electrostatic potential (blue: positive, red: negative). Hirudin is shown as a blue backbone worm. Potential is calculated using the same polarizability for protein and solvent.

distribution of charged residues in the binding site of the proteolytic enzyme thrombin. Fig. 22.4.3.1(*b*) shows the resulting electrostatic potential distribution on the protein surface. The basic (positive) region in the fibrinogen binding site, which could be inferred from close inspection of the distribution of charged residues in Fig. 22.4.3.1(*a*), is clearly more apparent in the potential distribution. Fig. 22.4.3.1(*c*) shows the effect of increasing ionic strength on the potential distribution, shrinking the regions of strong potential. Fig. 22.4.3.1(*d*) is calculated assuming the same dielectric for the solvent and protein. The more uniform potential distribution compared to Fig. 22.4.3.1(*b*) shows the focusing effect that the low dielectric interior has on the field emanating from charges in active sites and other cleft regions.

22.4.3.2. Charge-transfer equilibria

Charge-transfer processes are important in protein catalysis, binding, conformational changes and many other functions. The primary examples are acid–base equilibria, electron transfer and ion binding, in which the transferred species is a proton, an electron or a salt ion, respectively. The theory of the dependence of these three equilibria within the classical electrostatic framework can be treated in an identical manner, and will be illustrated with acid–base equilibria. A titratable group will have an intrinsic ionization equilibrium, expressed in terms of a known intrinsic pK_a^0, where $pK_a^0 = -\log_{10}(K_a^0)$, K_a^0 is the dissociation constant for the reaction $\mathrm{H}^+A = \mathrm{H}^+ + A$ and A can be an acid or a base. The pK_a^0 is determined by all the quantum-chemical, electrostatic and environmental effects operating on that group in some reference state. For example, a reference state for the aspartic acid side-chain ionization might be the isolated amino acid in water, for which $pK_a^0 = 3.85$. In the environment of the protein, the pK_a will be altered by three electrostatic effects. The first occurs because the group is positioned in a protein environment with a different polarizability, the second is due to interaction with permanent dipoles in the protein, the third is due to charged, perhaps titratable, groups. The effective pK_a is given by

$$pK_a = pK_a^0 + (\Delta\Delta G^{\mathrm{rf}} + \Delta\Delta G^{\mathrm{perm}} + \Delta\Delta G^{\mathrm{tit}})/2.303kT, \tag{22.4.3.1}$$

where the factor of $1/2.303kT$ converts units of energy to units of pK_a. The first contribution, $\Delta\Delta G^{\mathrm{rf}}$, arises because the completely solvated group induces a strong favourable reaction field (see Section 22.4.2.3) in the high dielectric water, which stabilizes the charged form of the group. (The neutral form is also stabilized by the solvent reaction field induced by any dipolar groups, but to a lesser extent.) Desolvating the group to any degree by moving it into a less polarizable environment will preferentially destabilize the charged form of that group, shifting the pK_a by an amount

$$\Delta\Delta G^{\mathrm{rf}} = (1/2)\sum_i \left(q_i^d \Delta\varphi_i^{\mathrm{rf},\,d} - q_i^p \Delta\varphi_i^{\mathrm{rf},\,p}\right), \tag{22.4.3.2}$$

where q_i^p and q_i^d are the charge distributions on the group, $\Delta\varphi_i^{\mathrm{rf},\,p}$ and $\Delta\varphi_i^{\mathrm{rf},\,d}$ are the changes in the group's reaction potential upon moving it from its reference state into the protein, in the protonated (superscript p) and deprotonated (superscript d) forms, respectively, and the sum is over the group's charges. The contribution of the permanent dipoles is given by

$$\Delta\Delta G^{\mathrm{tit}} = \sum_i \left(q_i^d - q_i^p\right)\varphi_i^{\mathrm{perm}}, \tag{22.4.3.3}$$

where $\varphi_i^{\mathrm{perm}}$ is the interaction potential at the ith charge due to all the permanent dipoles in the protein, including the effect of screening. It is observed that intrinsic pK_a's of groups in proteins are rarely shifted by more than 1 pK_a unit, indicating that the effects of desolvation are often compensated to a large degree by the $\Delta\Delta G^{\mathrm{perm}}$ term (Antosiewicz *et al.*, 1994). The final term accounts for the contribution of all the other charged groups:

$$\Delta\Delta G^{\mathrm{tit}} = \sum_i \left(q_i^d \langle\varphi_i\rangle^d_{\mathrm{pH},\,c,\,\Delta V} - q_i^p \langle\varphi_i\rangle^p_{\mathrm{pH},\,c,\,\Delta V}\right), \tag{22.4.3.4}$$

where $\langle\varphi_i\rangle$ is the mean potential at group charge i from all the other titratable groups. The charge states of the other groups in the protein depend in turn on their intrinsic 'pK_a's', on the external pH if they are acid–base groups, the external redox potential, ΔV, if they are redox groups and the concentration of ions, c, if they are ion-binding sites, as indicated by the subscript to $\langle\varphi_i\rangle$. Moreover, the charge state of the group itself will affect the equilibrium at the other sites. Because of this linkage, exact determination of the complete charged state of a protein is a complex procedure. If there are N such groups, the rigorous approach is to compute the titration-state partition function by evaluating the relative electrostatic free energies of all 2^N ionization states for a given set of pH, c, ΔV. From this one may calculate the mean ionization state of any group as a function of pH, ΔV *etc*. For large N this becomes impractical, but various approximate schemes work well, including a Monte Carlo procedure (Beroza *et al.*, 1991; Yang *et al.*, 1993) or partial evaluation of the titration partition function by clustering the groups into strongly interacting sub-domains (Bashford & Karplus, 1990; Gilson, 1993; Yang *et al.*, 1993).

Calculation of ion-binding and electron-transfer equilibria in proteins proceeds exactly as for calculation of acid–base equilibria, the results usually being expressed in terms of an association constant, K_a, or a redox midpoint potential E_m (defined as the external reducing potential at which the group is half oxidized and half reduced, usually at pH 7), respectively.

22.4.3.3. Electrostatic contributions to binding energy

The electrostatic contribution to the binding energy of two molecules is obtained by taking the difference in total electrostatic energies in the bound (AB) and unbound $A + B$ states. For the linear case,

$$\Delta\Delta G^{\mathrm{elec}}_{\mathrm{bind}} = (1/2)\sum_i^{N_A} q_i^A(\varphi_i^{AB} - \varphi_i^A) + (1/2)\sum_j^{N_B} q_i^B(\varphi_j^{AB} - \varphi_j^B), \tag{22.4.3.5}$$

where the first and second sums are over all charges in molecule A and B, respectively, and φ^x is the total potential produced by $x = A$, B, or AB. From equation (22.4.3.5), it should be noted that the electrostatic free energy change of each molecule has contributions from intermolecular charge–charge interactions, and from changes in the solvent reaction potential of the molecule itself when solvent is displaced by the other molecule. Equation (22.4.3.5) allows for the possibility that the conformation may change upon binding, since different charge distributions may be used for the complexed and uncomplexed forms of A, and similarly for B. However, other energetic terms, including those involved in any conformational change, have to be added to equation (22.4.3.5) to obtain net binding free energy changes. Nevertheless, changes in binding free energy due to charge modifications or changes in external factors such as pH and salt concentration may be estimated using equation (22.4.3.5) alone. For the latter, salt effects are usually only significant in highly charged molecules, for which the nonlinear form for the total electrostatic energy, equation (22.4.2.4), must be used. The salt dependence of binding of drugs and proteins to DNA has been studied using this approach (Misra, Hecht *et al.*, 1994; Misra, Sharp *et al.*, 1994; Sharp *et al.*, 1995), including the pH dependence of drug binding (Misra & Honig, 1995). Other applications include the binding of sulfate to the sulfate binding protein (Åqvist *et al.*, 1991) and antibody and antigen interactions (Lee *et al.*, 1992; Slagle *et al.*, 1994).

Chapter 22.5. The relevance of the Cambridge Structural Database in protein crystallography

F. H. Allen, J. C. Cole and M. L. Verdonk

22.5.1. Introduction

At its inception in the late 1960s, the Cambridge Structural Database (CSD: Allen, Davies *et al.*, 1991; Kennard & Allen, 1993) was one of the first scientific databases for which numerical data were the primary objective of the compilation. Thus, the CSD provides not only a fully retrospective bibliography of the structure determination of organic and metallo-organic compounds, but also gives immediate access to the primary results of each diffraction experiment: the space group, cell dimensions and fractional coordinates that define each structure at atomic resolution. In the late 1960s, the world output of small-molecule structures was just a few hundred per year and it was possible to use existing printed compilations to ensure that the developing CSD was fully retrospective. Despite this comprehensive nature, it has taken time for the CSD to have significant scientific impact as a research tool in its own right, and to be recognized as a source of structural knowledge that is applicable across a broad spectrum of structural chemistry.

There are two reasons for this rather gradual uptake. First, it took time to devise and implement software for the validation and organization of the data. Secondly, and most importantly, it was necessary to develop software for database searching, particularly for locating chemical substructures, and for data analysis and visualization. It was not until the late 1970s that the first comprehensive software systems became available and began to be widely distributed to scientists in academia and industry. Nevertheless, a number of highly influential database analyses were performed prior to 1980, and the proper numerical analysis and statistical treatment of bulk geometrical data began to receive attention (see *e.g.* Murray-Rust & Bland, 1978; Murray-Rust & Motherwell, 1978; Taylor, 1986). This software and its successors at last allowed the types of geometrical surveys, analyses and tabulations carried out manually by early practitioners such as Pauling (1939), Sutton (1956, 1959) and Pimental & McClellan (1960) to be executed automatically in a few minutes of increasingly powerful CPU time.

The early development of applications software simultaneously with methods for the acquisition and validation of new structural data was crucial for the CSD. Developments in structure-determination theory, allied to technological improvements in data collection and the ever increasing speed and capacity of modern computers, led to such a rapid expansion that the archive of May 1999 now contains more than 200 000 crystal structures, a total that doubles approximately every seven years. The literature is now so vast, so chemically diverse and so widely spread that it is virtually impossible for individual scientists to maintain current awareness without recourse to database facilities. It is now impossible to carry out viable systematic analyses without recourse to database technology. This chapter focuses primarily on the structural knowledge that is provided by such analyses, and that is relevant to the determination, refinement, validation and systematic study of macromolecular structures. However, the validity of these results depends crucially on two factors: the *completeness* of the archive and the *accuracy* with which the data are recorded. Hence, it is appropriate to preface the chapter with some comparative comment on these fundamental issues as they apply to the small-molecule and macromolecular structure archives.

22.5.2. The CSD and the PDB: data acquisition and data quality

22.5.2.1. Statistical inferences

With a current total of 200 000 structures and a doubling period of seven years (Fig. 22.5.2.1*a*), we may expect at least half a million small-molecule crystal structures to be in the CSD by the year 2010. The Protein Data Bank (PDB) (Abola *et al.*, 1997; Berman *et al.*, 2000), which began operations in the mid-1970s, and the Nucleic Acid Database (NDB) (Berman *et al.*, 1992) are the international repositories for macromolecular structure information. Input to the PDB was initially slow but is now showing a rapid growth rate reminiscent of the CSD of the 1970s (Fig. 22.5.2.1*b*). The PDB archive has a current total of *ca* 8500 structures (mid-1999) and a doubling period of close to two years. As with the CSD, this early *high rate* of growth will almost certainly decrease, thus increasing the doubling period. Nevertheless, by the year 2010, we might expect the PDB to contain more than 100 000 structures.

22.5.2.2. Data acquisition and completeness

Given the size and diversity of the CSD, it is amazing that searches for some common chemical substructures often yield far fewer hits than might have been expected. Sometimes, the absence of just a few key CSD entries would have negated a successful systematic analysis: some points in a graph would have been missing and a correlation would not have been detected. Similarly, completeness of the PDB is vital for the future of 'data mining' or 'knowledge engineering' in the macromolecular arena.

Data acquisition by the PDB has always had one valuable advantage in comparison with the CSD. The volume of numerical data generated by a protein structure determination is far too large for primary publication or hard-copy deposition. Thus, the PDB has always acquired data through direct deposition in electronic form, and authors have usually been involved in the validation of their entries. Further, it is a mandatory requirement of the vast majority of journals, and a clear recommendation of appropriate professional organizations, that prior deposition with the PDB is an essential precursor to primary publication. This key involvement of the PDB in the publication process acts as a vital guarantee of the completeness of the archive. The prior-deposition rule must be rigidly adhered to for the long-term benefit of science.

22.5.2.3. Standard formats: CIF and mmCIF

The CSD, on the other hand, reflects the published literature, and much of its data content has been re-keyboarded from hard-copy material. The Cambridge Crystallographic Data Centre (CCDC) is now beginning to receive significant amounts of electronic input, a development that owes much to the rapid international acceptance of an agreed standard electronic interchange format, the crystallographic information file or CIF (Hall *et al.*, 1991), and the rapid incorporation of CIF generators within most major structure solution and refinement packages. The CIF offers many advantages, some of which are only just being addressed within the CSD: (*a*) a clear definition of input data items and their representation; (*b*) a significant reduction in time spent correcting simple typographical errors; and (*c*) the possibility of enhancing the overall database content through the electronic availability of *all* information from the analysis, *i.e.* more than could reasonably be re-typed from hard-copy material. For the PDB, the recent adoption of the macromolecular CIF (mmCIF) as the agreed international standard offers similar advantages. This development, together with advances in communications technology, now make it possible to automate the deposition process more effectively, but the advantages of mmCIF can only be fully realized once it also becomes a standard output format of all of the relevant software packages.

22.5.2.4. Structure validation

The value of research results derived from the CSD and the PDB depends crucially on the accuracy of the underlying data [see *e.g.* Hooft *et al.* (1996) with respect to protein data]. As with the early CSD, much current research involves use of data from the developing PDB to establish rules and protocols for the validation of new protein structures (see *e.g.* Laskowski *et al.*, 1993). This activity, in turn, means that earlier entries in the archive may have to be reassessed periodically to bring their representations into line with best current practice. This sequence of events was commonplace in the CSD of the 1970s and, even now, new structure types entering the CSD can still provoke a reassessment of subclasses of earlier entries.

Secondly, it is important that errors and warnings raised by validation software have clear meanings and that validation results are clearly encoded within each entry. The end user can then make informed choices about which entries to include (or not) in any given application. Recent moves to apply a range of agreed and unambiguous primary checks to new data, and to require resolution of any problems prior to the issue of a publication ID code, represent an important development.

22.5.3. Structural knowledge from the CSD

22.5.3.1. The CSD software system

Structural knowledge from the CSD is reflected principally in the geometries of individual molecules, extended crystal structures and, most importantly, through systematic studies of the geometrical characteristics of large subsets of related substructural units. Software facilities for search, retrieval, analysis and visualization of CSD information as of 2001 are fully described in Chapter 24.3 of the first edition of this volume. The system allows for the calculation of a very wide range of geometrical parameters, both intramolecular and intermolecular. Most importantly, chemical substructural search fragments may be specified using normal covalent bonding definitions (single, double, triple *etc.*), limiting non-covalent contact distances and other geometrical constraints. For each instance of a search fragment located in the CSD, the system will compute a user-defined set of geometrical descriptors. The full matrix, $G(N, p)$, of the p geometrical parameters for each of the N fragments located in the CSD can then be analysed using numerical, statistical and visualization techniques to display individual parameter distributions, to compute medians, means and standard deviations, and to examine the geometrical data for correlations or discrete clusters of observations that may exist in the p-dimensional parameter space.

22.5.3.2. CSD structures and substructures of relevance to protein studies

Table 22.5.3.1 presents statistics for the 3137 structures of amino acids and peptides that are available in the CSD of April 1998 (containing 181 309 entries). Although this represents less than 2% of CSD information, some may consider that these are the only entries of real interest in molecular biology. In certain cases, *e.g.* for the derivation of very precise molecular dimensions and for some conformational work, this may be true. However, the real issue concerns the *transferability* of CSD-derived information to the protein environment. It is the biological relevance of a chemical *substructure* (inter- or intramolecular) that is important, and this consideration immediately brings much larger subsets of CSD entries into play. Information such as van der Waals radii can be derived from the CSD as a whole, while more specific information concerning, for example, biologically important metal coordination geometries can be derived from appreciable subsets of the total database, as shown in the statistics of Table 22.5.3.2.

22.5.3.3. Geometrical parameters of relevance to protein studies

Precise geometrical knowledge from atomic resolution studies of small molecules is important in the macromolecular domain since it provides: (*a*) geometrical restraints and standards to be applied during protein structure determination, refinement and validation; (*b*) model geometries for liganded small molecules and information about their preferred modes of interaction with

the host protein; (*c*) details of metal coordination spheres and geometries that are likely to be observed in metalloproteins; and (*d*) information from which force field and other parameters may be derived. Thus, the types of study discussed in this chapter are concerned with retrieving systematic knowledge concerning:

(1) molecular dimensions: bond lengths and valence angles;
(2) conformational features: torsion angles that describe acyclic and cyclic systems;
(3) metal coordination-sphere geometries: coordination numbers, metal–ligand distances and inter-ligand valence angles;
(4) general non-bonded contact distances: van der Waals radii;
(5) hydrogen-bond geometries: distances, angles, directional properties;
(6) other non-bonded interactions: identification and geometrical description;
(7) formation of preferred atomic arrangements or motifs involving non-covalent interactions.

In this short overview, which deals with such a broad range of structural information, our literature coverage is, of necessity, highly selective. In each area, we have tried to cite the more recent papers, from which leading references to earlier studies can be located. We also draw attention to a number of recent monographs in which a variety of CSD analyses are comprehensively cited and discussed: *Structure Correlation* (Bürgi & Dunitz, 1994), *Crystal Structure Analysis for Chemists and Biologists* (Glusker *et al.*, 1994), *Hydrogen Bonding in Biological Structures* (Jeffrey & Saenger, 1991) and *Crystal Engineering: the Design of Organic Solids* (Desiraju, 1989). Finally, we note the CCDC's own database of published research applications of the CSD. The DBUSE database currently contains literature references and short descriptive abstracts for nearly 700 papers. It forms part of each biannual CSD release and is fully searchable using the *Quest3D* program.

22.5.4. Intramolecular geometry

22.5.4.1. Mean molecular dimensions

The work of Pauling (1939) represented the first systematic attempt to derive mean values for bond lengths and valence angles from the limited structural data available at that time. This work resulted in the definition of covalent bonding radii for the common elements and had a seminal influence on the development of chemistry over the past half century. Further tabulations appeared sporadically until the publication in 1956 and 1959 of the major compilation *Tables of Interatomic Distances and Configuration in Molecules and Ions,* edited by Sutton (1956, 1959), by The Chemical Society of London. Kennard (1962) extended the available data for bonds between carbon and other elements.

In the mid-1980s, the CCDC and its collaborators compiled updated tables of mean bond lengths for both organic (Allen *et al.*, 1987) and organometallic and metal coordination compounds (Orpen *et al.*, 1989). Both compilations were based on the CSD of September 1985 containing 49 854 entries. Of these, 10 324 organic structures and 9802 organometallics or metal complexes satisfied a variety of secondary selection criteria, and were used in the analysis. For each bond length, both compilations present the mean, its estimated standard deviation and the sample standard deviation, together with the median value of the distribution and its upper and lower quartile values. The organic section describes 682 discrete chemical bond types involving 65 element pairs. Of these, 511 (75%) involve carbon, and 428 (63%) involving only carbon, nitrogen and oxygen are relevant to protein studies. The organometallic and metal complex compilation presents similar statistics for 325 different bond types involving *d*- and *f*-block metals. It is planned to automate and systematize the production of such tabulations, so that they can be dynamically updated in computerized form, as part of CCDC's ongoing development of knowledge-based structural libraries.

More recently, Engh & Huber (1991) have generated sets of mean bond lengths and valence angles from peptidic structures retrieved from the 80 000 entries then available in the CSD. Their compilations are based on 31 atom types which are most appropriate to the protein environment and are well represented in CSD structures. These authors note that such knowledge, together with torsional and other information, is vital to the determination, refinement and validation of protein structures. Prior to their detailed CSD analysis, some of the parameters used for these purposes had been determined with a lower accuracy than was required by the diffraction data. For this reason, and particularly for use with higher-resolution protein data, they recommend that the most accurate parameters possible should always be used.

Systematic use of CSD data generates mean values together with standard deviations for both the sample and the mean. The sample standard deviations provide information about the spread of each parameter distribution, *i.e.* information about the variability of each parameter which can be parameterized as force constants. Comparative refinements of selected proteins showed that the new CSD-based parameters yielded significant improvements in R factors and in geometry statistics. Finally, Engh & Huber (1991) remark that their results should be updated regularly as the quantity and quality of data in the CSD increase with time. Apart from producing more precise estimates of mean values, incorporation of more protein-relevant atom types into the schema should then be possible.

22.5.4.2. Conformational information

Torsion angles are the natural measures of conformational relationships within molecules. If we specify a chemical substructure involving a central bond of interest, then the CSD system will display the distribution of torsion angles about that bond, computed from the tens, hundreds, or even thousands of instances located in the database. Examination of these *univariate distributions* will reveal any conformational preferences that may exist in small-molecule crystal structures. This approach is illustrated by the histogram of Fig. 22.5.4.1, which shows the torsional distribution about S—S bridge bonds in C(sp^3)—S—S—C(sp^3) substructures located in the CSD. Clearly, there is a preference for a perpendicular conformation in the CS—SC unit. This corresponds well with values observed for cysteine bridges in protein structures, and with theoretical calculations on small model compounds.

The interrelationship between two torsion angles can be visualized by plotting them against each other on a conventional 2D scattergram. In the small-molecule area, the distribution of data points in these scattergrams can reveal conformational interconversion pathways (Rappoport *et al.*, 1990) or show areas of high data density corresponding to conformational preferences (Schweizer & Dunitz, 1982). The best known *bivariate distribution* is the Ramachandran plot of peptidic φ–ψ angles, which is universally used to assess the quality of protein structures and to identify structural features. Ashida *et al.* (1987) performed an extensive analysis of peptide conformations available in the CSD and present torsional histograms, a Ramachandran plot, and a variety of other visual and descriptive statistics that summarize this data set.

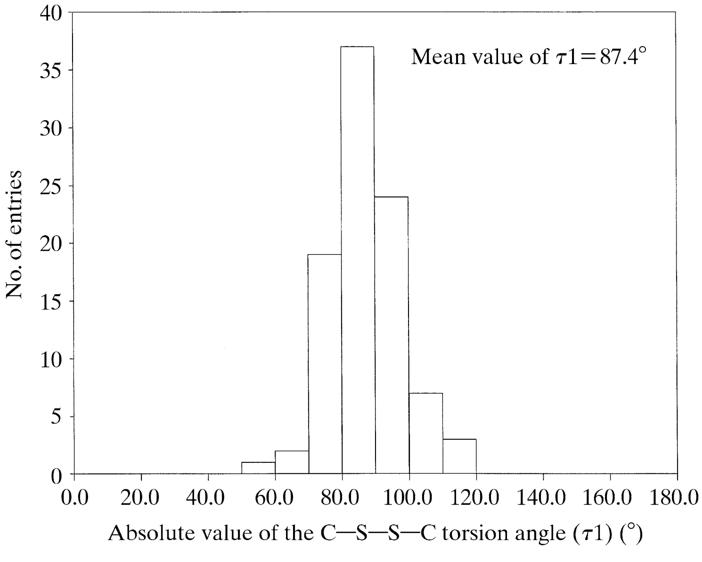

Figure 22.5.4.1
Distribution of torsion angles in C(sp^3)—S—S—C(sp^3) substructures located in the CSD.

It is often necessary to use three or more torsion angles to define the conformation of, *e.g.*, a side chain or flexible ring. Here, *multivariate* statistical techniques (Chatfield & Collins, 1980; Taylor, 1986) have proved valuable for extracting information from the matrix $T(N, k)$ that contains the k torsion angles computed for each of the N examples of the substructure in the CSD. Two methods, both available within the CSD system software described in Chapter 24.3 of the first edition of this volume, are commonly used to visualize the k-dimensional data set and to locate natural sub-groupings of data points within it.

Principal component analysis (PCA) (Murray-Rust & Motherwell, 1978; Allen, Doyle & Auf der Heyde, 1991; Allen, Howard & Pitchford, 1996) is a dimension-reduction technique which analyses the variance in $T(N, k)$ in terms of a new set of uncorrelated, orthogonal variables: the principal components, or PCs. The PCs are generated in decreasing order of the percentage of the variance that is explained by each of them. The hope is that the number of PCs, p, that explains most of the variance in the data set is such that $p \ll k$, so that a few pairwise scatter plots with respect to the new PC axes will provide useful visualizations of the complete data set. For cyclic fragments, PCA results are closely related to those obtained using the ring-puckering methodology of Cremer & Pople (1975). Cluster analysis (CA) (Everitt, 1980; Allen, Doyle & Taylor, 1991) is a purely numerical method that attempts to locate discrete groupings of data points within a multivariate data set. CA uses 'distances' or 'dissimilarities' between pairs of points in a k-dimensional space as its working basis, and a very large number of clustering algorithms exist. The mathematical basis of both of these techniques, the modifications that are needed to account for topological symmetry in the search fragment and examples of their application have been reviewed by Taylor & Allen (1994).

Preliminary work using the concepts of machine learning (Carbonell, 1989) for knowledge discovery and classification have also been carried out using the CSD (see *e.g.* Allen *et al.*, 1990; Fortier *et al.*, 1993). In particular, conceptual clustering methods have been applied to a number of substructures (Conklin *et al.*, 1996) and the results compared with those obtained by the statistical and numerical methods described above. Similar techniques are also being used for the classification of protein structures (see *e.g.* Blundell *et al.*, 1987).

22.5.4.3. Crystallographic conformations and energies

Crystallographic conformations obviously represent energetically accessible forms. However, for use in molecular-modelling applications, the key question must be asked: Are the condensed-phase crystallographic observations a good guide to conformational preferences in other phases? The indications are that the answer is 'yes' from the types of studies exemplified or cited in the previous section: there appears to be a clear *qualitative* relationship between crystallographic conformer distributions and the low-energy features of the appropriate potential energy hypersurface, although the estimation of absolute energies from the relative populations of these distributions is not appropriate (Bürgi & Dunitz, 1988).

Allen, Harris & Taylor (1996) addressed this question in a systematic manner for a series of 12 one-dimensional (univariate) conformational problems. All of the chosen substructures [simple derivatives of ethane, involving a single torsion angle (τ) about the central C—C bond] were expected to show one symmetric (*anti*, $\tau \simeq 180^\circ$) energy minimum and two symmetry-related asymmetric (*gauche*, $\tau \simeq \pm 60^\circ$) minima. For each substructure, the crystallographic torsional distribution was determined from the CSD and compared with the 1D potential-energy profile, computed using *ab initio* molecular-orbital methods and the 6–31G* basis set. Close agreement was observed between the experimental condensed phase results and the computed *in vacuo* data. Taken over all 12 substructures, the *ab initio* optimized values of the asymmetric (*gauche*) torsion angle vary from <55° to >80°, and a scatter plot of these optimized values *versus* the mean crystallographic values for *gauche* conformers is linear, with a correlation coefficient of 0.831. Two other results of the study were that: (*a*) torsion angles with higher strain energies (>4.5 kJ mol^{-1}) are rarely observed in crystal structures (<5%); and (*b*) taken over many structures, conformational distortions due to crystal packing appear to be the exception rather than the rule.

22.5.4.4. *Conformational libraries*

In essence, the CSD can be regarded as a huge library of individual molecular conformations. However, to be of general value, it is necessary to distil, store and present this knowledge in an ordered manner, in the form of torsional distributions for specific atomic tetrads $A—B—C—D$. Protein-specific libraries of this type derived from high-resolution PDB structures are commonly used as aids to protein structure determination, refinement and validation (Bower *et al.*, 1997; Dunbrack & Karplus, 1993). The information can either be stored in external databases, or hardwired into the program in the form of rules. However, CSD usage has tended to concentrate on analyses of individual substructures, as noted above, both for their intrinsic interest and to develop novel methods of data analysis. Recently, Klebe & Mietzner (1994) have described the generation of a small library containing 216 torsional distributions derived from the CSD, together with 80 determined from protein–ligand complexes in the PDB. The library was used in a knowledge-based approach for predicting multiple conformer models for putative ligands in the computational modelling of protein–ligand docking. Conformer prediction is accomplished by the computer program *MIMUMBA*. As part of its programme for the development of knowledge-based libraries from the CSD, the CCDC has now embarked on the generation of a more comprehensive torsional library. Here, information is being hierarchically ordered according to the level of specificity of the chemical substructures for which torsional distributions are available in the library.

22.5.4.5. *Metal coordination geometry*

Some 54% of the information content of the CSD relates to organometallics and metal complexes. This reflects the crucial role of single-crystal diffraction analyses in the renaissance of inorganic chemistry since the 1950s, and the fundamental importance of the technique in characterizing the many novel molecules synthesized over the past 40 years. Since ligands containing nitrogen, oxygen and sulfur are ubiquitous, the CSD contains much information that is relevant to the binding of metal ions by proteins [*e.g.* zinc (Miller *et al.*, 1985), calcium (Strynadka & James, 1989) *etc.*]. Some statistics for the occurrence of some common metals having N and/or O ligands are presented in Table 22.5.3.2.

One of the earliest studies (Einspahr & Bugg, 1981) concerned the geometry of Ca–carboxylate binding, with special reference to biological systems. Since that time, a variety of other studies of biologically relevant metal coordination modes have appeared from the laboratories of Glusker, Dunitz and others (see *e.g.* Glusker, 1980; Chakrabarti & Dunitz, 1982; Carrell *et al.*, 1988, 1993; Chakrabarti, 1990*a*,*b*). These studies show, *inter alia*, that α-hydroxycarboxylates and imidazoles such as histidine tend to bind metal ions in their planes, but that alkali metal cations tend to bind carboxylate groups indiscriminately both in-plane and out-of-plane. Chapter 17 of Glusker *et al.* (1994) is a significant source of additional information and leading references to work in this area over the past two decades.

22.5.5. Intermolecular data

Non-bonded interaction geometries observed in small-molecule crystal structures are of great value in the determination and validation of protein structures, in furthering our understanding of protein folding, and in investigating the recognition processes involved in protein–ligand interactions. The CSD continues to provide vital information on all of these topics.

22.5.5.1. *van der Waals radii*

The hard-sphere atomic model is central to chemistry and molecular biology and, to an approximation, atomic van der Waals radii can be regarded as transferable from one structure to another. They are heavily used in assessing the general correctness of all crystal-structure models from metals and alloys to proteins. Pauling (1939) was the first to provide a usable tabulation for a wide range of elements, but the values of Bondi (1964) remain the most highly cited compilation in the modern literature. His values, assembled from a variety of sources including crystal-structure information, were selected for the calculation of molecular volumes and, in his original paper, Bondi (1964) issues a caution about their general validity for the calculation of limiting contact distances in crystals. In view of the huge amount of non-bonded contact information available in the CSD, Rowland & Taylor (1996) recently tested Bondi's statement as it might apply to the common nonmetallic elements, *i.e.* H, C, N, O, F, P, S, Cl, Br and I. They found remarkable agreement (within 0.02 Å) between the crystal-structure data and the Bondi values for S and the halogens, and agreement within 0.05 Å for C, N and O (new values all larger). The only significant discrepancy was for H, where averaged neutron-normalized small-molecule data yield a van der Waals radius of 1.1 Å, 0.1 Å shorter than the Bondi (1964) value. In the specific area of amino-acid structure, Gould *et al.* (1985) have studied the crystal environments and geometries of leucines, isoleucines, valines and phenylalanines. Their work provides estimates of minimum non-bonded contact distances and indicates the preferred van der Waals interactions of these primary building blocks.

22.5.5.2. *Hydrogen-bond geometry and directionality*

The hydrogen bond is the strongest and most frequently studied of the non-covalent interactions that are observed in crystal structures. As with intramolecular geometries, the first surveys of non-bonded interaction geometries all concerned hydrogen bonds, and were reported long before the CSD existed (Pauling, 1939; Donohue, 1952; Robertson, 1953; Pimentel & McClellan, 1960). The review by Donohue (1952) already contained a plot of N···O distances *versus* C—N···O angles in crystal structures (the C—N groups are terminal charged amino groups), while the review by Pimentel & McClellan (1960)

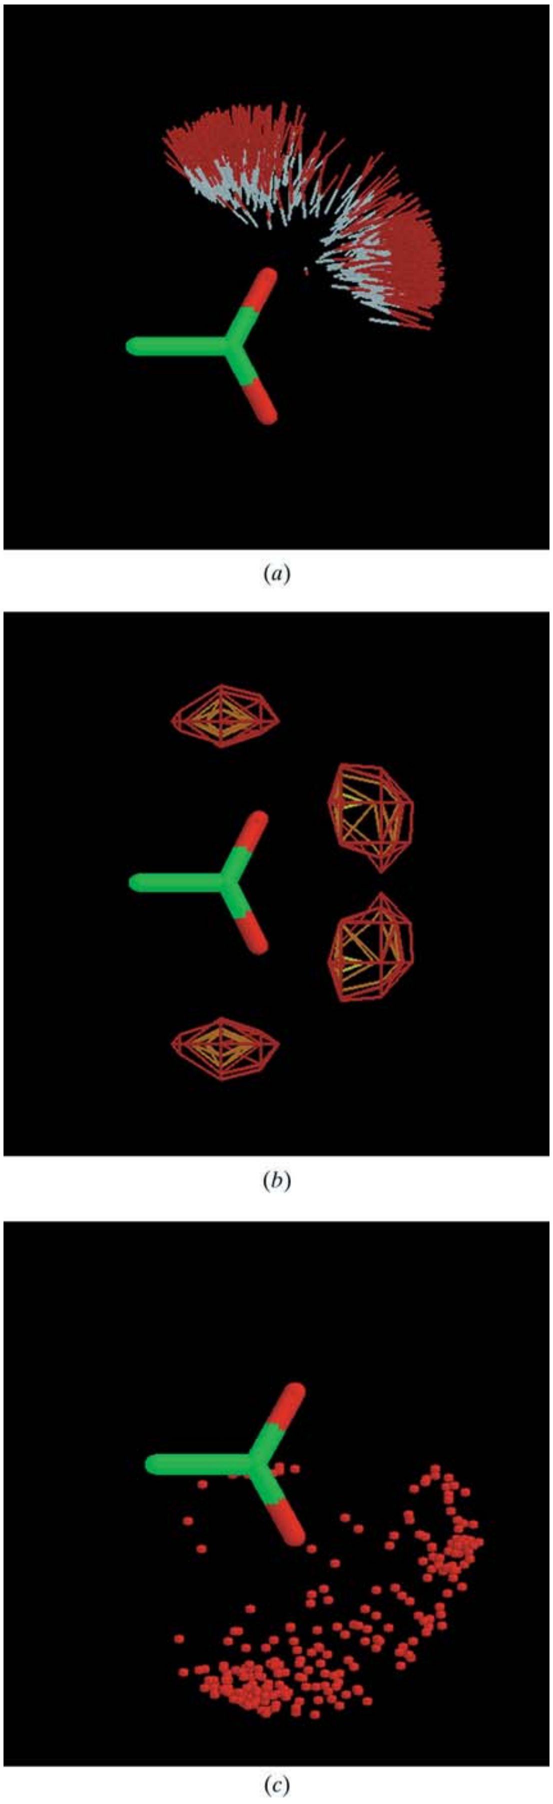

Figure 22.5.5.1
The IsoStar knowledge-based library of intermolecular interactions: interaction of O—H donors (contact groups) with one of the >C═O acceptors of a carboxylate group (the central group). (*a*) Direct scatter plot derived from CSD data, (*b*) contoured scatter plot derived from CSD data and (*c*) direct scatter plot derived from PDB data.

contained histograms of hydrogen-bond distances. Up to the mid-1970s, numerous other studies appeared, *e.g.* Balasubramanian *et al.* (1970), Kroon & Kanters (1974) and Kroon *et al.* (1975), in which all of the statistical analyses were performed manually.

With the advent of the CSD and its developing software system, these kinds of studies became much more accessible and easier to perform, although the non-bonded search facility was only generalized and fully integrated within *Quest3D* in 1992. Thus, Taylor and colleagues reported studies on N—H···O═C hydrogen bonds (Taylor & Kennard, 1983; Taylor *et al.*, 1983, 1984*a*,*b*), Jeffrey and colleagues reported detailed studies on the O—H···O hydrogen bond (Ceccarelli *et al.*, 1981), hydrogen bonds in amino acids (Jeffrey & Maluszynska, 1982; Jeffrey & Mitra, 1984), and hydrogen bonding in nucleosides and nucleotides, barbiturates, purines and pyrimidines (Jeffrey & Maluszynska, 1986), while Murray-Rust & Glusker (1984) studied the directionalities of O—H···O hydrogen bonds to ethers and carbonyls. These studies indicated that hydrogen bonds are often very directional. For example, the distribution of the O—H···O hydrogen-bond angle, after correction for a geometrical factor, peaks at 180° (*i.e.* there is a clear preference for linear hydrogen bonds) and, in carbonyls and carboxylate groups, hydrogen bonds tend to form along the lone-pair directions of the O-atom acceptors (Fig. 22.5.5.1). For ethers, however, lone-pair directionality is not observed, as is illustrated in Fig. 22.5.5.2.

Software availability has facilitated CSD studies of a wide range of individual hydrogen-bonded systems in the recent literature, including studies of resonance-assisted hydrogen bonds (Bertolasi *et al.*, 1996) and resonance-induced hydrogen bonding to sulfur (Allen, Bird *et al.*, 1997*a*). These statistical studies are often combined with molecular-orbital calculations of interaction energies. Some of these studies are cited in this chapter, but the monograph of Jeffrey & Saenger (1991) and the CCDC's DBUSE database are valuable reference sources.

22.5.5.3. *C—H···X hydrogen bonds*

An important and often underestimated interaction in biological systems is the C—H···*X* hydrogen bond. These bonds have been extensively studied in small-molecule crystal structures, especially in relation to the ongoing discussion as to whether or not they should be called hydrogen bonds. Although Donohue (1968) concluded that the question 'The C—H···O hydrogen bond: what is it?' had only one answer: 'It isn't', a survey of 113 neutron-diffraction structures showed clear statistical evidence for an attractive interaction between C—H groups and oxygen and nitrogen acceptors (Taylor & Kennard, 1982). Later, more evidence for this hypothesis was found, and it was even shown that some C—H···O interactions are directional (Berkovitch-Yellin & Leiserowitz, 1984; Desiraju, 1991; Steiner & Saenger, 1992; Desiraju *et al.*, 1993; Steiner *et al.*, 1996). A continuing area of interest has been to establish the relative donor abilities of C—H in different chemical environments, since spectroscopic data had indicated that donor ability decreased in the order $C(sp)$—H > $C(sp^2)$—H > $C(sp^3)$—H. This general hydrogen-acidity requirement was noted by Taylor & Kennard (1982), and systematically addressed using CSD information by Desiraju & Murty (1987), and by Pedireddi & Desiraju (1992), who derived a novel scale of carbon acidity based on C···O separations in a wide variety of systems containing C—H···O hydrogen bonds. A recent paper (Derewenda *et al.*, 1995) highlights the importance of C—H···O═C bonds in stabilizing protein secondary structure.

22.5.5.4. O—H···π and N—H···π hydrogen bonds

Spectroscopic evidence for the existence of N,O—H···π hydrogen bonding to acetylenic, olefinic and aromatic acceptors is well documented (Joris *et al.*, 1968). To our knowledge, the first survey of these interactions in the CSD was carried out by Levitt & Perutz (1988), prompted by observations made in protein structures. A more recent CSD survey of this type of bonding (Viswamitra *et al.*, 1993) has shown that intermolecular examples are clearly observed and that these bonds, although very weak, can be both structurally and energetically significant. Recently, Steiner *et al.* (1995) have presented novel crystal structures, database evidence and quantum-chemical calculations on C≡C—H···π(C≡C) and π(phenyl) bonding. They cite H···C≡C (midpoint) distances as short as 2.51 Å and observe hydrogen-bond cooperativity in extended systems with hydrogen-bond energies in the range 4.2–9.2 kJ mol^{-1}. Finally, we note that electron-rich transition metals can act as proton acceptors in hydrogen-bond interactions with O—H, N—H and C—H donors. Brammer *et al.* (1995) have reviewed progress in this developing area.

22.5.5.5. Other non-covalent interactions

The hydrogen bond, $X(\delta-)$—$H(\delta+)\cdots Y(\delta-)$—$Z(\delta+)$, can be viewed as an (almost) linear dipole–dipole interaction, whose ubiquity in nature is due to the presence of many donor–hydrogen dipoles. In a recent review of supramolecular synthons and their application in crystal engineering, Desiraju (1995) illustrates the structural importance of a wide range of attractive non-bonded interactions that do not involve hydrogen mediacy, and notes the long-term value of the CSD in identifying and characterizing these interactions. The area of weak intermolecular interactions is now a burgeoning one in which the combination of CSD analysis and high-level *ab initio* molecular-orbital calculations is proving important in establishing both preferred geometries and estimates of interaction energies. In this context, the intermolecular perturbation theory (IMPT) of Hayes & Stone (1984), a methodology which is free of basis-set superposition errors, is proving particularly useful.

Some of the earliest CSD studies concerned the geometry and directionality of approach of N and O nucleophiles to carbonyl centres, leading to the mapping of (dynamic) reaction pathways through systematic analysis of many examples of related (static) crystal structures (see Bürgi & Dunitz, 1983, 1994). This work was also extended to a study of the directional preferences of non-bonded atomic contacts at sulfur atoms, initially using S in amino acids but later including other examples of divalent sulfur (Rosenfield *et al.*, 1977). It was shown that C—S—C groups tend to bind positively charged electrophiles in directions that are approximately perpendicular to the C—S—C plane, while negatively charged nucleophiles prefer to bind to S along an extension of one of the C—S bonds.

The strong tendency for halogens X = Cl, Br and I to form short contacts to other halogens, and especially to electronegative O and N atoms (Nyburg & Faerman, 1985) is well known (Price *et al.*, 1994). Recent combined CSD/IMPT studies of C—X···O═C (Lommerse *et al.*, 1996) and C—X···O(nitro) (Allen, Lommerse *et al.*, 1997) systems showed a marked preference for the X···O interaction to form along the extension of the C—X bond, with interaction energies in the range −7 to −10 kJ mol^{-1}. These interactions have been used (Desiraju, 1995) to engineer a variety of novel small-molecule crystal structures, and the few X···O interactions observed in protein structures generally conform to the geometrical preferences observed in small-molecule studies.

Interactions involving other functional groups are also of importance, and Taylor *et al.* (1990) used CSD information to construct composite crystal-field environments for carbonyl and nitro groups in their search for isosteric replacements in modelling protein–ligand interactions. Their work showed that many of the short intermolecular contacts made by carbonyl groups are to other carbonyl groups in the extended crystal structure. More recently, Maccallum *et al.* (1995*a*,*b*) have demonstrated the importance of Coulombic interactions between the C and O atoms of proximal CONH groups in proteins as an important factor in stabilizing α-helices, β-sheets and the right-hand twist often observed in β-strands. Their calculations indicate an attractive carbonyl–carbonyl interaction energy of about −8 kJ mol^{-1} in specific cases, and they remark that these interactions are *ca* 80% as strong as the CO···HN hydrogen bonds within their computational model. Allen, Baalham *et al.* (1998) have used combined CSD/IMPT analysis in a more detailed study of carbonyl–carbonyl interactions and have shown that (*a*) the interaction is commonly observed in small-molecule structures; (*b*) that the preferred interaction geometry is a dimer motif involving two antiparallel C···O interactions, although numerous examples of a perpendicular motif (one C···O interaction) were also observed; and that (*c*) the total interaction energies for the antiparallel and perpendicular motifs are about −20 and −8 kJ mol^{-1}, respectively, the latter value being comparable to that computed by Maccallum *et al.* (1995*a*,*b*). In studies with protein structures, it has also been noted that carbonyl–carbonyl interactions stabilize the partially allowed Ramachandran conformations of asparagine and aspartic acid (Deane *et al.*, 1999)

22.5.5.6. Intermolecular motif formation in small-molecule crystal structures

Desiraju (1995) has stressed that the design process in crystal engineering depends crucially on the high probabilities of formation of certain well known intermolecular motifs, *e.g.* the hydrogen-bonded dimer frequently formed by pairs of carboxylate groups. By analogy with molecular synthesis, he describes these general non-covalent motifs (which often contain strong hydrogen bonds) as supramolecular *synthons*, and points to their importance in supramolecular chemistry as a whole (see *e.g.* Lehn, 1988; Whitesides *et al.*, 1995). Since protein–protein and protein–ligand interactions are also supramolecular phenomena, it follows that information about common interaction motifs is also of importance in structural biology. A computer program is now being written at the CCDC to establish the topologies, chemical constitutions and probabilities of formation of intermolecular motifs directly from the CSD. Initial results (Allen, Raithby *et al.*, 1998; Allen *et al.*, 1999) provide statistics for the most common cyclic hydrogen-bonded motifs, and it is likely that motif information will be included in the developing IsoStar knowledge-based library described in Section 22.5.5.8.

22.5.5.7. *The answer 'no'*

Previous sections have illustrated the location and characterization of some important non-covalent interactions. Equally important is a knowledge of when such interactions *do not* occur although chemical sensibility might indicate that they should. We provide four examples from the CSD: (*a*) only 4.8% of more than 1000 thioether S atoms form hydrogen-atom contacts that are within van der Waals limits, despite the obvious analogy with the potent acceptor C—O—C (Allen, Bird *et al.*, 1997*b*); (*b*) of 118 instances in which a furan ring coexists with N—H or O—H donors, the O atom forms hydrogen bonds on only three occasions (Nobeli *et al.*, 1997); (*c*) the ester oxygen $(R_1)(\mathrm{O}{=})\mathrm{C}{-}\underline{\mathrm{O}}{-}R_2$ almost never forms strong hydrogen bonds, although the adjunct carbonyl oxygen atom is well known as a highly potent acceptor (Lommerse *et al.*, 1997); and (*d*) covalently bound fluorine atoms rarely form hydrogen bonds (Dunitz & Taylor, 1997).

22.5.5.8. *IsoStar: a library of non-bonded interactions*

The previous sections show that the amount of data in the CSD on intermolecular geometries is vast, and CSD-derived information for a number of specific systems is available in the literature at various levels of detail. If not, the CSD must be searched for contacts between the relevant functional groups. To provide structured and direct access to a more comprehensive set of derived information, a knowledge-based library of non-bonded interactions (IsoStar: Bruno *et al.*, 1997) has been developed at the CCDC since 1995. IsoStar is based on experimental data, not only from the CSD but also from the PDB, and contains some theoretical results calculated using the IMPT method. Version 1.1 of IsoStar, released in October 1998, contains information on non-bonded interactions formed between 310 common functional groups, referred to as *central groups*, and 45 *contact groups*, *e.g.* hydrogen-bond donors, water, halide ions *etc.* Information is displayed in the form of scatter plots for each interaction. Version 1.1 contains about 12 000 scatter plots: 9000 from the CSD and 3000 from the PDB. IsoStar also reports results for 867 theoretical potential-energy minima.

For a given contact between between a central group (A) and a contact group (B), CSD search results were transformed into an easily visualized form by overlaying the A moieties. This results in a 3D distribution (scatter plot) showing the experimental distribution of B around A. Fig. 22.5.5.1(*a*) shows an example of a scatter plot: the distribution of OH groups around carboxylate anions, illustrating hydrogen-bond formation along the lone-pair directions of the carboxylate oxygens. The IsoStar software provides a tool that enables the user to inspect quickly the original crystal structures in which the contacts occur *via* a hyperlink to the original CSD entries. This is very helpful in identifying outliers, motifs and biases. Another tool generates contoured surfaces from scatter plots, which show the density distribution of the contact groups. A similar approach was first used by Rosenfield *et al.* (1984). Contouring aids the interpretation of the scatter plot and the analysis of preferred geometries. Fig. 22.5.5.1(*b*) shows the contoured surface of the scatter plot in Fig. 22.5.5.1(*a*); the lone-pair directionality now becomes even more obvious.

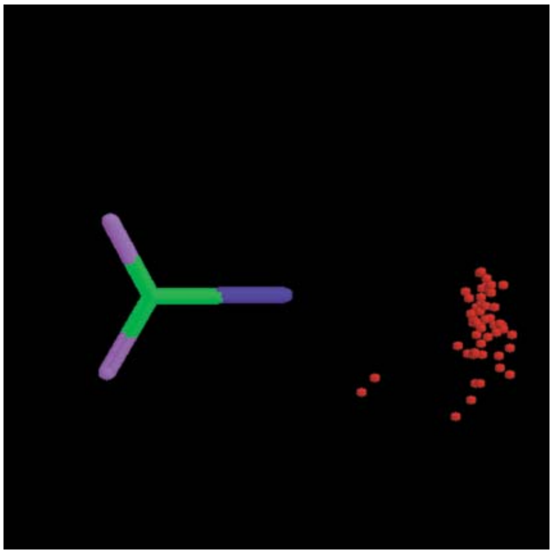

Figure 22.5.5.3
Distribution of oxygen atoms around C(aromatic)—I (CSD data from the IsoStar library, see text).

The fact that carboxylate anions form hydrogen bonds along their lone-pair directions may be well known, although force fields do not always use this information. However, the IsoStar library also contains information on many less well understood functional groups. The interaction between aromatic halo groups and oxygen atoms (Lommerse *et al.*, 1996) is referred to above, and Fig. 22.5.5.3 shows the distribution of oxygen acceptor atoms around aromatic iodine groups. It is clear that the contact O atoms are preferentially observed along the elongation of the C—I bond.

The PDB scatter plots in IsoStar only involve interactions between non-covalently bound ligands and proteins, *i.e* side chain–side chain interactions are excluded. Similar work was presented by Tintelnot & Andrews (1989), but at that time the PDB contained only 40 structures of protein–ligand complexes. The IsoStar library contains data derived from almost 800 complexes having a resolution better than 2.5 Å. Fig. 22.5.5.1(*c*) shows an example of a scatter plot from the PDB (the distribution of OH groups around carboxylate groups). Here, although the hydrogen atoms are missing in the PDB plot, the close similarity between Figs. 22.5.5.1(*c*) (PDB) and 22.5.5.1(*a*) (CSD) is obvious.

22.5.5.9. *Protein–ligand binding*

The reluctance to use data from the CSD because they do not relate directly to biological systems has been noted earlier. However, in principle, the same forces that drive the inclusion of a new molecule into a growing crystal should also apply to the

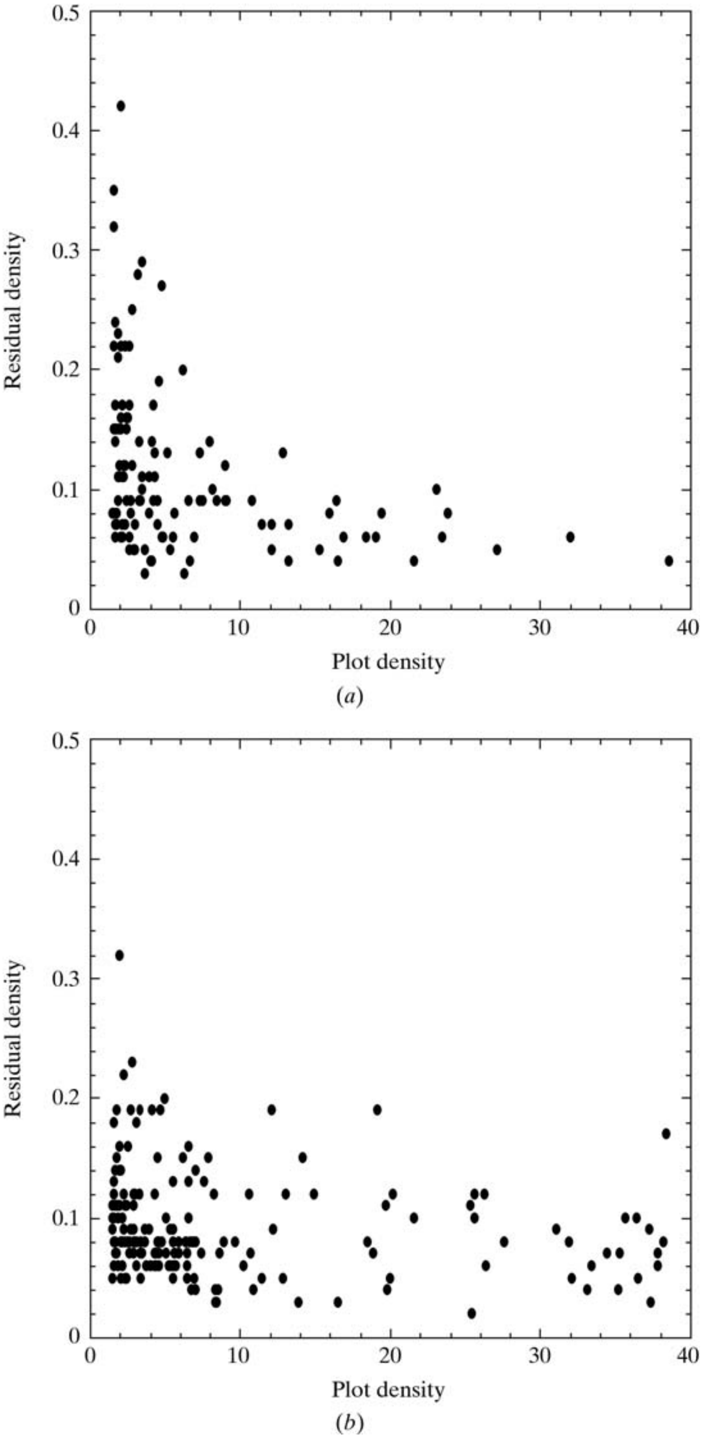

Figure 22.5.5.4
Pairwise comparison of intermolecular-interaction density maps from the CSD and the PDB. Plots of *residual density* $|\rho(\text{CSD}) - \rho(\text{PDB})|$ *versus plot density*, *i.e.* the average density in the least dense situation (CSD or PDB), for situations where the protonation state of the central group is (*a*) unambiguous, and (*b*) ambiguous.

binding of a ligand to a protein. In both cases, molecule and target need to be de-solvated first (although in the first case not necessarily from a water environment) and then interact in the most favourable way.

Nicklaus and colleagues suggested that on average, the conformational energy of ligands in the protein-bound state is 66 (48) kJ mol^{-1} above that of the global minimum-energy conformation *in vacuo* (Nicklaus *et al.*, 1995). This result was based on 33 protein–ligand complexes from the PDB for which the ligand also occurs in a small-molecule structure in the CSD. The same investigation also showed that, although ligand conformations in the protein-bound state are generally different from those observed in small-molecule crystal structures, on average the conformational energy of the ligand in the CSD crystal-structure conformation is 66 (47) kJ mol^{-1} above that of the global minimum-energy conformation *in vacuo*, although Boström *et al.* (1998) have shown that these conformational energies are much lower if calculated in a water environment. The computational work indicates that the forces that affect the conformation of a ligand are of comparable magnitude at a protein binding site to those in a small-molecule crystal-structure environment. Thus, if small-molecule crystal-structure statistics tell us that a given structure fragment can only adopt one conformation, generally there is no reason to believe that a ligand that contains this fragment will adopt a different conformation when it binds to a protein.

In principle, the information on non-bonded interactions derived from the CSD and assembled in the IsoStar library should be very important for the understanding and prediction of interaction geometries. However, in light of the comments above, it is important to know whether these data *are* generally relevant to interactions that occur in the protein binding site. Work by Klebe (1994) indicated that, at least for a limited set of test cases, the geometrical distributions derived from ligand–protein complexes are similar to those derived from small-molecule crystal structures. Since the IsoStar library contains information from both the PDB and the CSD, it provides the ultimate basis for establishing similarities (or not) between the interaction geometries observed in small-molecule crystal structures and those observed in protein–ligand complexes. Comparing CSD scatter plots with their corresponding plots from the PDB is an obvious way of establishing the relevance of non-bonded interaction data from small-molecule crystal structures to biological systems.

A full systematic comparison of PDB and CSD scatter plots or, more accurately, of PDB and CSD *density maps* has recently been performed by Verdonk (1998). He calculated residual densities, obtained by subtracting one density map from the other, for each pair of density maps. It appears that, in general, CSD and PDB plots (and thus interaction geometries) are very similar indeed: the average residual density is only 10 (10)%, indicating that 90% of the density in the PDB map is also observed in the CSD map. In Fig. 22.5.5.4(*a*), the average residual densities of each PDB–CSD comparison are plotted *versus* the average concentration of contact groups in the scatter plot. The filled circles represent comparisons for which the protonation state of the central group is unambiguous (*i.e.* carboxylic acid, imidazole *etc.* were excluded). It appears that the residual density decreases with the amount of data in the plots, obviously caused by the more accurate calculation of the residual density. The 'true' residual density seems to be as low as about 6%.

Fig. 22.5.5.4(*b*) shows a similar graph, but now for those density maps in which the protonation state of the central group is ambiguous. As expected, the spread in the calculated residual densities is much higher, even for very dense plots. By comparing the density map from the PDB with the CSD maps for the different protonation states of the central group, the most frequent protonation state of this central group in the protein structures can be predicted. In Table 22.5.5.1, for example, the residual densities for protein carboxylic acid groups are shown, compared with the CSD plots of the neutral carboxylic acid and with those of the charged carboxylate anion. In all cases, the residual density is lower if the PDB map is compared with the CSD map for charged carboxylate anions. This indicates that the

Table 22.5.5.1
Residual densities for carboxylic acid groups

The PDB density maps are compared with the CSD maps for uncharged carboxylic acid and for charged carboxylate anions.

	Residual density (CCO_2H)	Residual density ($CCOO^-$)
Any (N,O,S)—H	0.06	0.04
Any N—H nitrogen	0.07	0.05
Any O—H oxygen	0.07	0.05
Non-donating oxygen	0.12	0.04
Carbonyl oxygen	0.13	0.07
Carbonyl carbon	0.12	0.04
Water oxygen	0.07	0.05
Any aliphatic C—H carbon	0.08	0.06

majority of glutamate and aspartate side chains are charged, which is consistent with other evidence.

22.5.5.10. Modelling applications that use CSD data

Predicting binding modes of ligands at protein binding sites is a problem of paramount importance in drug design. One approach to this problem is to attempt to dock the ligand directly into the binding site. There are several protein–ligand docking programs available, *e.g. DOCK* (see Kuntz *et al.*, 1994), *GRID* (Goodford, 1985), *FLExX* and *FLExS* (Rarey *et al.*, 1996; Lemmen & Lengauer, 1997), and *GOLD* (Jones *et al.*, 1995, 1997). The docking program *GOLD*, developed by the University of Sheffield, Glaxo Wellcome and the CCDC, and which has the high docking success rate of 73%, uses a small torsion library, based on the data from the CSD, to explore the conformational space of the ligand. Its hydrogen-bond geometries and fitness functions are also partly based on CSD data. In the future, we intend to create a more direct link between the crystallographic data and the docking program, *via* IsoStar and the developing torsion library.

Another approach to the prediction of binding modes is to calculate the energy fields for different probes at each position of the binding site, for instance using the *GRID* program (Goodford, 1985). The resulting maps can be displayed as contoured surfaces which can assist in the prediction and understanding of binding modes of ligands. CCDC is developing a program called *SuperStar* (Verdonk *et al.*, 1999) which uses a similar approach to that of the *X-SITE* program (Singh *et al.*, 1991; Laskowski *et al.*, 1996). However, *SuperStar* uses non-bonded interaction data from the CSD rather than the protein side chain–side chain interaction data employed in *X-SITE*. Thus, for a given binding site and contact group (probe), *SuperStar* selects the appropriate scatter plots from the IsoStar library, superimposes the scatter plots on the relevant functional groups in the binding site, and transforms them into one composite probability map. Such maps can then, for example, be used to predict where certain functional groups are likely to interact with the binding site. The strength of *SuperStar* is that it is based entirely on experimental data (although this is also the cause of some limitations). The fields simply represent what has been observed in crystal strucures. We are currently verifying *SuperStar* on a test set of more than 100 protein–ligand complexes from the PDB and preliminary results are encouraging.

Finally, CSD data are used in several *de novo* design programs. These types of programs, *e.g. LUDI* (Böhm, 1992*a*,*b*), predict novel ligands that will interact favourably with a given protein and use hydrogen-bond geometries from the CSD (indirectly) to position their structural fragments in the binding site.

22.5.6. Conclusion

This chapter has summarized the vast range of structural knowledge that can be derived from the small-molecule data contained in the CSD. We have attempted to show that much of this knowledge is directly transferable and applicable to the protein environment. Far from being discrete, structural studies of small molecules and proteins have a natural synergy which, if exploited creatively, will lead to significant advances in both areas. It is therefore unsurprising that some of these CSD studies have been prompted by initial observations made on proteins.

As a result of this activity, it is now very clear that software access to the information stored in the CSD and the PDB must be at two levels: a raw-data level and a derived-knowledge level. The onward development of structural knowledge bases from the underlying data provides for the preservation and storage of the results of data-mining experiments, thus avoiding repetition of standard experiments and providing instant access to complex derivative information. Most importantly, a suitably structured knowledge base can be acted on by software tools that are designed to solve complex problems in structural chemistry (see *e.g.* Thornton & Gardner, 1989; Allen *et al.*, 1990; Bruno *et al.*, 1997; Jones *et al.*, 1997). The availability of knowledge bases derived from experimental observations is likely to be a crucial factor in the solution of those two analogous, and currently intractable, problems in the small-molecule and protein-structure domains: crystal structure and polymorph prediction on the one hand, and protein folding on the other.

PART 23. STRUCTURAL ANALYSIS AND CLASSIFICATION

Chapter 23.1. Protein-fold classification

C. Orengo and J. Thornton

Since the first structure of myoglobin was solved in 1971, there has been an exponential growth in known protein structures with about 73 000 structures currently deposited in the Protein Data Bank (PDB; Abola *et al.*, 1987) and 500 or more solved each month. Structural genomics (SG) initiatives are now contributing significantly to this total; between 2005 and 2008 they accounted for some 18% of new structures, and, now that high-throughput pipelines have been set up, some 600–800 structures deposited to the PDB per year (around two structures a day) are from SG centres around the world (Rajesh *et al.*, 2009). When dealing with such large numbers it is necessary to organize the data in a manageable and biologically meaningful way. To this end, several structural classifications have been developed [SCOP (Murzin *et al.*, 1995), CATH (Orengo *et al.*, 1997), DALI (Holm & Sander, 1999), 3Dee (Barton, 1997), HOMSTRAD (Mizuguchi *et al.*, 1998) and ENTREZ (Hogue *et al.*, 1996)], differing in their methodology and the degree of structural and functional annotation for the protein families identified.

Most public classification schemes have chosen to group proteins according to similarities in their domain structures, as this is generally considered to be the important evolutionary and folding unit. However, it can be difficult to identify domain boundaries either manually or using automatic algorithms, and although there are many methods available, it has been shown that even the most reliable algorithms only give the correct answer about 80% of the time (Jones *et al.*, 1998). Methods for recognizing domains are described in Chapter 23.2.

Most protocols used for clustering protein domain structures into families first identify similarities in their sequences. There are many well established methods for doing this, most based on dynamic programming algorithms, and since proteins with sequence identities of 30% or more are known to adopt very similar folds (Sander & Schneider, 1991; Flores *et al.*, 1993), it is relatively simple to cluster related proteins into evolutionary families on this basis. Very distant relatives (<20% sequence identity) are not easily identified by sequence alignment, but since structure is much more highly conserved during evolution, these relationships can be detected by comparing the 3D structures directly.

Various powerful algorithms have been developed for recognizing structurally related proteins (for reviews see Holm & Sander, 1994; Brown *et al.*, 1996). These build on the rigid-body superposition methods of Rossmann & Argos (1975), which compare intermolecular distances after optimal translation and rotation of one protein structure onto the other. Other methods are based on the distance plots developed by Phillips (1970), which enable comparison of intramolecular distances between protein structures. In comparing very distantly related proteins, there are a number of problems which must be overcome. Insertions or deletions can obscure equivalent regions, though generally these appear in the loops between secondary structures. Residue substitutions can cause shifts in the orientations of the secondary structures in order to maintain optimal hydrophobic packing in the core.

A number of strategies have been developed for handling these problems. For example, some methods only consider secondary-structure elements, as these will contain fewer insertions. Artymiuk *et al.* (1989) represent secondary structures as linear vectors and use fast, efficient comparison algorithms based on graph theory. Others have adapted rigid-body methods to optimally superpose secondary structures, ignoring loops. Some methods chop the proteins being compared into fragments and then use various energy-minimization approaches (*e.g.* simulated annealing, Monte Carlo optimization) to link equivalent fragments in the two proteins. Such fragments can be identified by rigid-body superposition (Vriend & Sander, 1991) or, in the case of the DALI method (Holm & Sander, 1994), by comparing contact maps for hexapeptide fragments. Several groups have modified the dynamic programming algorithms designed to cope with insertions or deletions in sequence comparison in order to compare three-dimensional (3D) information (Taylor & Orengo, 1989; Sali & Blundell, 1990; Russell & Barton, 1993). For example, the SSAP method of Taylor & Orengo (1989) uses double dynamic programming to align residue structural environments defined by vectors between Cβ atoms, whilst in STAMP (Russell & Barton, 1993) dynamic programming is used in an iterative procedure, together with rigid-body superposition.

Once equivalent residues have been found, the degree of structural similarity between two proteins can be measured in a number of ways, though the most commonly used is the root-mean-square deviation (RMSD), which is effectively the average 'distance' between superposed residues. However, there is still no consensus about which thresholds might imply homologous proteins or fold similarity between analogous proteins or common structural motifs. It is likely that this will become clearer as more structures are determined and the families become more highly populated, providing more information on tolerance to structural changes. These contraints will probably reflect functional requirements and/or kinetic or thermodynamic factors and will be specific to the family.

Several groups (Holm & Sander, 1999; Hogue *et al.*, 1996) attempt to determine the significance of a structural match by considering the distribution of scores for unrelated proteins and calculating a Z score. These approaches are very reliable for proteins possessing unusual structural characteristics but may not be as sensitive for those with highly recurring and common structural motifs. Other groups use empirical approaches (Orengo *et al.*, 1997) to establish reasonable cutoffs for identifying homologues, though these approaches obviously suffer from the currently limited size of the structure data bank.

Because of the individual strategies used to recognize relatives, the protein-structure classifications differ somewhat in their assignments. However, most classifications group proteins having highly similar sequences ($\geq$30%) into families. Subsequently,

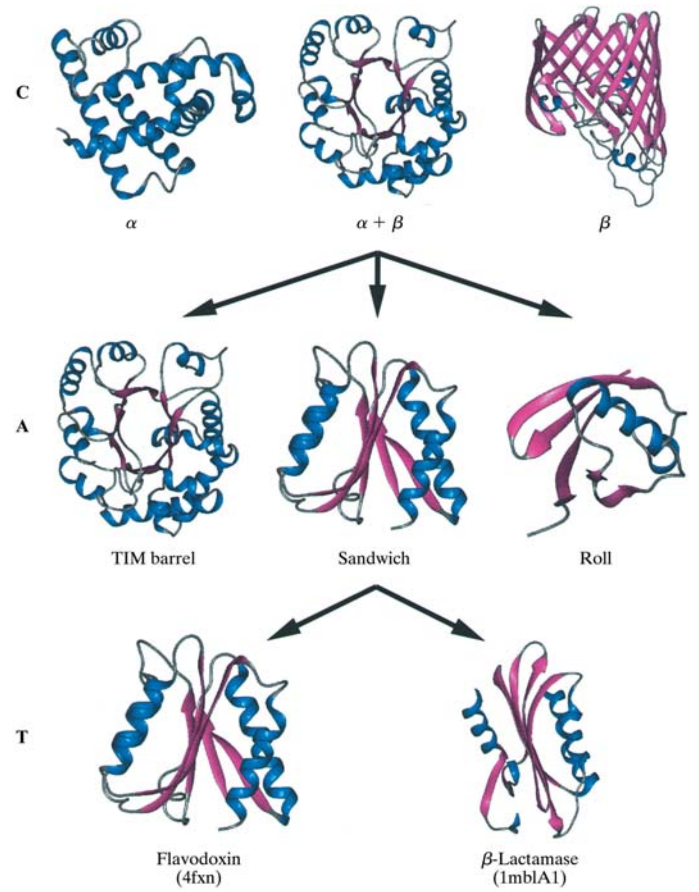

Figure 23.1.1
Schematic representation of the (C)lass, (A)rchitecture and (T)opology/fold levels in the CATH database.

those families having highly similar structures and some other evidence of common ancestry [*e.g.* similar functions or some residual sequence identity (Orengo *et al.*, 1999)] are merged into homologous superfamilies. Families adopting similar folds, but where there is no other evidence to suggest divergent evolution, are usually put into the same fold group but are described as analogous proteins, since their similarity may simply reflect the physical and/or chemical constraints on protein folding.

Recent analysis of CATH superfamilies has shown that some of the most highly populated superfamilies in CATH are structurally very diverse. Typically, domain relatives possess a common 'structural core' but secondary structural embellishments to this core can be considerable and effectively result in homologous structures varying in size by threefold or more and having rather different global folds (Reeves *et al.*, 2006; Greene *et al.*, 2007; Cuff *et al.*, 2009). This poses some challenges to hierarchical domain structure classifications like SCOP and CATH. However, usually the evolutionary conserved cores of relatives within a domain superfamily possess highly similar folds.

SCOP and CATH are currently the largest of the public classifications, each with over 1900 homologous superfamilies. In SCOP (Murzin *et al.*, 1995), these families have been very carefully manually validated using biochemical information and by consideration of special structural features (*e.g.* rare β-bulges, left-handed helical connections) that may constitute evolutionary fingerprints; in CATH, homologues are validated both manually and automatically (Orengo *et al.*, 1997). Other databases [HOMSTRAD (Mizuguchi *et al.*, 1998); 3Dee (Barton, 1997)] contain similar groupings of protein structures, and there are multiple structural alignments for the family, annotated according to residue properties.

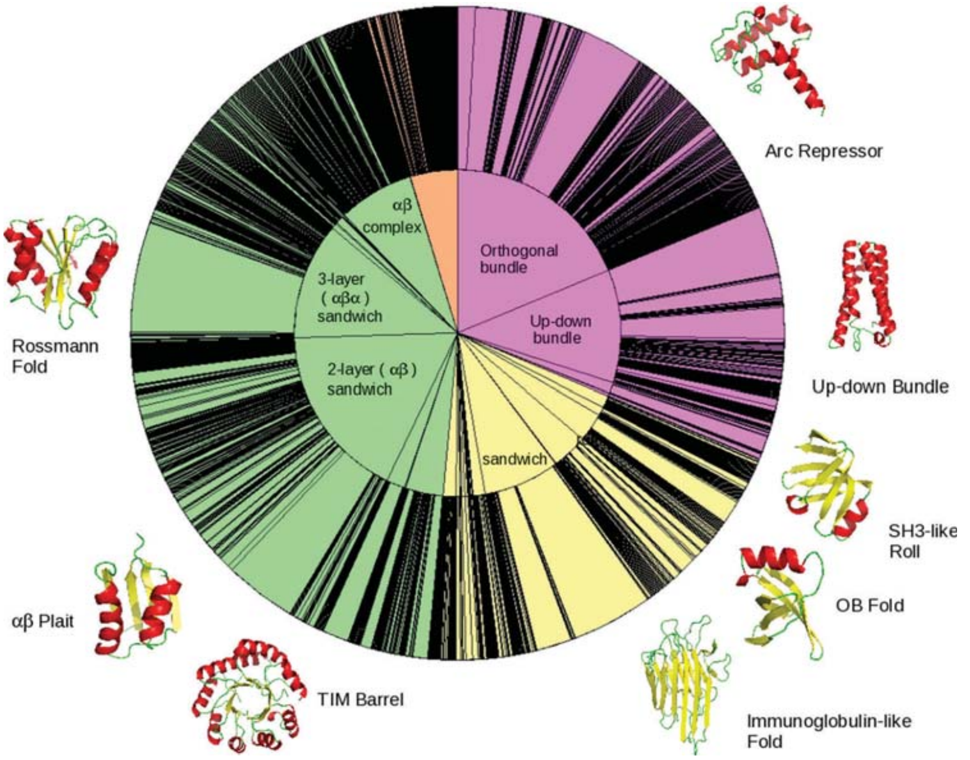

Figure 23.1.2
'CATHerine wheel' plot showing the distribution of non-homologous structures [*i.e.* a single representative from each homologous superfamily (H level) in CATH] amongst the different classes (C), architectures (A) and fold families (T) in the CATH database. Protein classes are shown coloured as red (mainly α), green (mainly β), yellow (α–β) and orange (few secondary structures). Within each class, the angle subtended for a given segment reflects the proportion of structures within the identified architectures (inner circle) or fold groups (outer circle). *MOLSCRIPT* (Kraulis, 1991) illustrations are shown for representative examples from the superfold families.

Several studies have suggested a limited number of folds available to proteins, with estimates ranging from one thousand to several thousand (Chothia, 1993; Orengo *et al.*, 1994), and this will mean an increasing number of analogous protein pairs being identified as the structural genomics initiatives continue. Recent analyses of the population of different fold families have revealed that some folds are more highly populated, perhaps because they fold more easily or are more stable. In the CATH database, ten favoured folds, described as superfolds, comprised very regular, layered architectures and were shown to contain a higher proportion of favoured motifs (*e.g.* Greek key, $\beta\alpha$ motif) than non-superfold structures. Similarly, analysis of SCOP (Brenner *et al.*, 1996) revealed some 40 or so frequently occurring domains (FODS), which included the superfolds. About one-third of all non-homologous structures (<25% sequence identity to each other) adopt one of these folds.

Some groups avoid explicit definition of protein families. The DALI database of Holm & Sander (1999) is a neighbourhood scheme listing all related proteins for a given protein structure.

Neighbours are identified using the DALI structure-comparison algorithm (Holm & Sander, 1993) and range from the most highly similar, homologous proteins to those sharing only motif similarities. The ENTREZ database (Hogue *et al.*, 1996) provides a similar scheme, generated by the VAST structure-comparison method of Gibrat *et al.* (1997). Both allow the user to assess significance and draw their own inferences regarding evolutionary relationships. More recently, the DALI domain database (DDD) (Holm & Sander, 1998) has provided clusters of related proteins based on calculated Z scores.

Most available databases further classify the fold groups on the basis of class. These agree with the major classes recognized by Levitt & Chothia (1976) (mainly α, mainly β, α/β, $\alpha + \beta$), although in the CATH database the α/β and $\alpha + \beta$ classes have been merged (Fig. 23.1.1). CATH also describes an intermediate architecture level between class and fold group (Orengo *et al.*, 1997). This refers to the arrangement of secondary-structure elements in 3D, regardless of their connectivity, and so defines the shape (*e.g.* barrel, sandwich, propeller) (Fig. 23.1.2). There are currently 40 different architectures in CATH, with the simple barrel and sandwich shapes accounting for about 60% of the non-homologous structures.

Chapter 23.2. Locating domains in three-dimensional structures

L. Holm and C. Sander

23.2.1. Introduction

Modular design is beneficial in many areas of life, including computer programming, manufacturing, and even in protein folding.

Protein-structure analysis has long operated with the notion of domains, *i.e.*, dividing large structures into quasi-independent substructures or modules (Wetlaufer, 1973; Bork, 1992). In various contexts, these substructures are thought to fold autonomously, to carry specific molecular functions such as binding or catalysis, to move relative to each other as semi-rigid bodies and to speed the evolution of new functions by recombination (Fig. 23.2.1.1).

The problem of subdividing protein molecules into structural and functional units has received the attention of numerous researchers over the last 25 years. Early algorithms focused on protein folding or unfolding pathways and aimed at identifying substructures that would be physically stable on their own. Nowadays, with bulging macromolecular databases, the focus has shifted to devise automatic methods for identifying domains that can form the basis for a consistent protein-structure classification (Murzin *et al.*, 1995; Orengo *et al.*, 1997; Holm & Sander, 1999).

This review presents the concepts underlying computational methods for locating domains in three-dimensional structures. Those interested in implementations are referred to the web services of the European Bioinformatics Institute[1] and related sites.

23.2.2. Compactness

A variety of ingenious techniques have been invented for locating structural domains in 3D structures. These include inspection of distance maps, clustering, neighbourhood correlation, plane cutting, interface area minimization, specific volume minimization, searching for mechanical hinge points, maximization of compactness and maximization of buried surface area (Rossmann & Liljas, 1974; Rashin, 1976; Crippen, 1978; Nemethy & Scheraga, 1979; Rose, 1979; Schulz & Schirmer, 1979; Go, 1981; Lesk & Rose, 1981; Sander, 1981; Wodak & Janin, 1981; Zehfus & Rose, 1986; Kikuchi *et al.*, 1988; Moult & Unger, 1991; Holm & Sander, 1994; Zehfus, 1994; Islam *et al.*, 1995; Siddiqui & Barton, 1995; Swindells, 1995; Holm & Sander, 1996; Sowdhamini *et al.*, 1996; Zehfus, 1997; Holm & Sander, 1998; Jones *et al.*, 1998; Wernisch *et al.*, 1999).

Common to most approaches are the assumptions that folding units are compact and that the interactions between them are weak. These notions can be made quantitative, for example, by counting interatomic contacts and by locating domain borders by identifying groups of residues such that the number of contacts between groups is minimized. The hierarchic organization of putative folding units can be inferred starting from the complete structure and recursively cutting it (*in silico*) into smaller and smaller substructures. Alternatively, one may start from the residue or secondary-structure-element level and successively associate the most strongly interacting groups. The procedure involves two optimization problems.

The first optimization problem is algorithmic and concerns finding the optimal subdivisions. This problem is complicated by the possibility of the chain passing several times between domains (discontinuous domains). Without the constraint of sequential continuity, there is a combinatorial number of possibilities for dividing a set of residues into subsets (Zehfus, 1994). This hurdle has been overcome by fast heuristics (Holm & Sander, 1994*b*; Zehfus, 1997; Wernisch *et al.*, 1999).

The second optimization problem concerns formulating physical criteria that distinguish between autonomous and nonautonomous folding units, *i.e.*, defining termination criteria for recursive algorithms. Since compactness-related criteria do not have a clear bimodal distribution, domain-assignment algorithms (Holm & Sander, 1994*b*; Islam *et al.*, 1995; Siddiqui & Barton, 1995; Swindells, 1995; Sowdhamini *et al.*, 1996; Wernisch *et al.*, 1999) use cutoff parameters that have been fine-tuned against an external reference set of domain definitions.

23.2.3. Recurrence

Most fold classifications use a hierarchical model where evolutionary families are a subcategory of fold type and it is natural to assume that domain boundaries should be conserved in evolution. Consistency concerns lead to a reformulation of the goals of the domain-assignment problem, away from (imprecise) physical models of stable folding units and towards recognizing such units phenomenologically in the database of known structures through recurrence. The concept of recurrence has long been the cornerstone of domain assignments by experts based on visual inspection (Richardson, 1981). Recurrence means recognizing architectural units in one protein that have already been defined (named) in another.

The practical importance of domain identification is illustrated by the discoveries made by a systematic structure comparison of recurrent domains between histidine triad (HIT) proteins and galactose-6-phosphate uridylyltransferase [homodimer and internally duplicated common catalytic core, respectively (Holm & Sander, 1997)], and between beta-glucosyltransferase and glycogen phosphorylase [bare and heavily decorated common catalytic core, respectively (Holm & Sander, 1995; Artymiuk *et al.*, 1995)], even though the contours of the molecules look quite different.

Let us restate the goal of domain identification as an economic description of all known protein structures in terms of a small set of large substructures. This is an intuitive goal and conceptually related to the principle of minimal encoding in information theory. The key ingredients of the optimization problem are the gain associated with reusing a substructure and the cost associated with using many small substructures to describe a protein. An analogy in writing is that copying blocks of text is cheap, but for coherence some thought and effort is necessary for bridging the blocks.

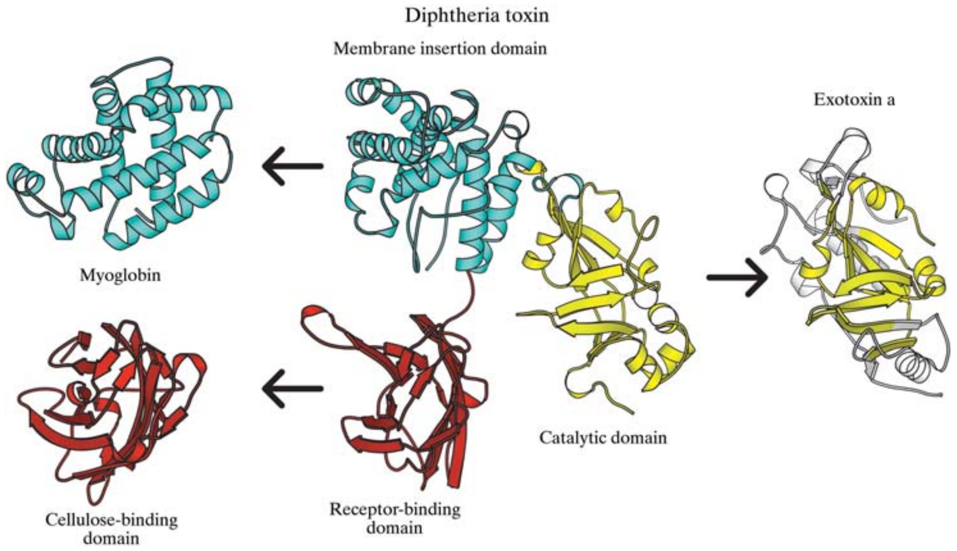

Figure 23.2.1.1
The structure of diphtheria toxin (Bennett & Eisenberg, 1994) beautifully illustrates domains as structural, functional and evolutionary units. Structurally, note the compact globular shape of each domain and the flexible linkers between them. Functionally, note how each domain carries out a different stage of infection by the bacterium: receptor binding, membrane penetration and ADP-ribosylation of the target protein. Evolutionarily, note the occurrence of domains homologous to the catalytic domain of diphtheria toxin in exo-, entero- and pertussis toxins, and in poly-ADP-ribose polymerase (Holm & Sander, 1999). Arrows point to recurrent substructures in structural neighbours (Lionetti *et al.*, 1991; Li *et al.*, 1996; Tormo *et al.*, 1996) of each domain of diphtheria toxin. Drawn using *MOLSCRIPT* version 2 (Kraulis, 1991).

With a suitably defined cost function, recurrence can be used to select an optimal set of substructures from the hierarchic folding or unfolding trees generated using compactness criteria. Thus, the unsatisfactorily solved problem of defining termination criteria for compactness algorithms can be turned into an optimization problem that does not rely on any external reference and leads to an internally consistent set of domain definitions.

The key difficulty is in quantifying the notion of economy so that it leads to a selection of substructures of 'appropriate' size, *i.e.*, globular folds and not, for example, supersecondary-structure motifs. One solution, which is physical nonsense but has the desired qualitative behaviour, is a heuristic objective function used in the DALI domain dictionary (Holm & Sander, 1998). Recurrence is quantified in terms of the statistical significance of structural similarity for many pairs of substructures. The statistical significance is highest for structural similarities that involve large units and that completely cover a substructure unit. Exploiting these effects, a sum-of-pairs objective function is defined that favours recurrences of large substructures with distinct topological arrangements and packing of secondary-structure elements, and disfavours small substructures consisting of one or two secondary-structure elements despite their higher frequency of recurrence. Though other formulations of the optimization problem are possible, this empirically chosen objective function combined with a heuristic algorithm for optimization yields a useful set of substructures (domains).

23.2.4. Conclusion

While we do not foresee that automatically delineated domains will be accepted as the gold standard of the trade, modern methods, based on a combination of recurrence and compactness criteria, yield domain definitions that are consistent within protein families and often coincide with biologically functional units, recover the well known folding topologies with many members, produce clusters with good coverage of common secondary-structure elements, and provide a useful basis for large-scale structure analysis and classification.

Chapter 23.3. Protein–ligand interactions

A. E. Hodel and F. A. Quiocho

23.3.1. Introduction

There are currently over a thousand unique protein-bound ligands described in the Protein Data Bank, illustrating the enormous variety of small molecules with which proteins interact. These ligands serve as cofactors in protein-mediated reactions, substrates in these reactions, and elements that maintain or alter protein structure or macromolecular assembly. The specific binding of small molecules to proteins is a primary means by which living systems interact and exchange information with their environment. The atomic details of protein–ligand interactions are often quite similar to the intramolecular interactions observed within a protein molecule. Examples of all the various non-covalent interactions described in Parts 20 and 22, such as hydrogen bonds, van der Waals forces and other electrostatic phenomena, are observed between proteins and their small-molecule ligands.

Through the diverse interactions observed between proteins and their ligands, a few fundamental patterns of recognition emerge. In general, ligand binding requires that the protein partially or fully sequesters the ligand from the solvent. This demands that the energy of interaction between the protein and the ligand must be strong enough to overcome the interactions between both species and the solvent as well as the translational and rotational entropy which is lost upon fixing the orientation of the ligand relative to the protein. The protein achieves this level of interaction by presenting a binding site that is complementary to the ligand both in shape and electrostatic functionality. Beyond this generalization, each ligand has its own unique and complicated story. Rather than attempt to summarize the enormous subject of protein–ligand interactions in a comprehensive manner, we will instead illustrate several of the unique interactions observed between proteins and other molecules.

23.3.2. Protein–carbohydrate interactions

The interaction between proteins and carbohydrates provides a prototypic example of how proteins specifically recognize small organic ligands. Protein-mediated recognition of carbohydrates is crucial in a diverse array of processes, including the transport, biosynthesis and storage of carbohydrates as an energy source, signal transduction through carbohydrate messengers, and cell–cell recognition and adhesion (Rademacher *et al.*, 1988). Many aspects of protein–carbohydrate recognition are observed in the interactions of proteins with other small-molecule ligands. For example, carbohydrate recognition is largely conferred through a combination of hydrogen bonding and van der Waals interactions with the protein (Quiocho, 1986). These interactions are generally presented in a binding site that is highly complementary to the target ligand in shape and functionality. Carbohydrate-binding proteins also occasionally employ ordered water molecules and bound metal ions to facilitate ligand recognition (Quiocho *et al.*, 1989; Vyas, 1991; Weis & Drickamer, 1996). There are also many examples of 'induced fit' recognition of carbohydrates, where the binding of the ligand induces a conformational change in the protein. This phenomenon of ligand-induced conformational change was observed in one of the first ligand–protein interactions visualized by X-ray crystallography, namely the binding of a carbohydrate substrate to lysozyme (Blake *et al.*, 1967). Since these early studies, a wide variety of carbohydrate–protein structures have been determined, and a number of general themes have emerged from this continually active field (Vyas, 1991). These themes are further applicable in the general study of protein–ligand recognition.

Two general classes of carbohydrate-binding modes have been observed in their complexes with proteins (Quiocho, 1986; Vyas, 1991). The first group of proteins completely sequester the carbohydrate from the surrounding solvent. These proteins, including the periplasmic proteins and the catalytic site of glycogen phosphorylase, tend to have a high affinity for their ligand ($K_d \simeq 10^{-6}$–10^{-7}). The high affinity of these proteins can be attributed to the entropic gain of desolvating the protein and carbohydrate surfaces as well as the exceptionally high degree of functional complementarity in the ligand-binding site. The periplasmic proteins nearly saturate the hydrogen-bonding potential of their carbohydrate ligands (Quiocho, 1986). The second group of proteins bind their ligands in shallow clefts in the solvent-exposed protein surface. This mode of binding, observed in the lectins, lysozyme and the storage site of glycogen phosphorylase, generally has a lower binding constant than the first class of binding proteins ($K_d \simeq 10^{-3}-10^{-6}$). Some members of this second class of proteins, such as the lectins, are able to increase the affinity for their ligands dramatically by clustering a number of low-affinity sites through the oligmerization of the polypeptides (Weis & Drickamer, 1996). The specific arrangement of lectin oligomers allows them to discriminate between large cell-surface arrays of polysaccharides with high affinity and selectivity.

23.3.2.1. Carbohydrate recognition at the atomic level

An early review of protein–carbohydrate interactions revealed several atomic level interactions that continue to appear ubiquitously in the structures of protein–carbohydrate complexes (Quiocho, 1986). A generic cyclic sugar in mono- or oligosaccharides appears to be recognized as a disc that displays two flat non-polar surfaces surrounded by a ring of polar hydroxyls. Proteins recognize these features by hydrogen bonding to the ring of polar hydroxyls while stacking flat aromatic side chains against the non-polar disc faces.

Cooperative hydrogen bonding, where the hydroxyl group of a carbohydrate participates as both a donor and acceptor of hydrogen bonds, is often observed in the direct interactions between proteins and carbohydrate ligands (Fig. 23.3.2.1). The sp^3-hybridized oxygen atom of a carbohydrate hydroxyl may act as both an acceptor of two hydrogen bonds through the two lone pairs of electrons as well as a donor of a single hydrogen bond. Cooperative hydrogen bonding generally follows a simple pattern in which the carbohydrate hydroxyl accepts a hydrogen bond from a protein amide group while simultaneously donating a hydrogen bond to a protein carbonyl oxygen. Hydrogen bonding to protein hydroxyl groups is observed only infrequently.

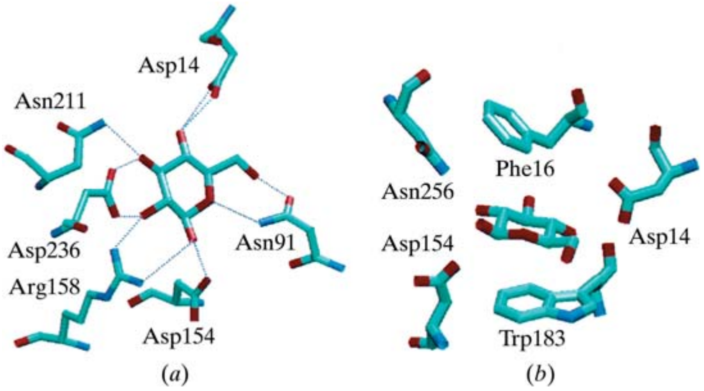

Figure 23.3.2.1
The atomic recognition of carbohydrates by a protein. The environment of glucose bound to the galactose/glucose binding protein is shown (Vyas *et al.*, 1988). (*a*) The ring of hydrogen bonds around the polar edge of the sugar molecule. Note the 'bidentate' hydrogen bonds with Asp236, Arg158 and Asn91. As the hydroxyl groups 1, 2 and 3 simultaneously donate and accept hydrogen bonds from protein side chains, they are involved in 'cooperative' hydrogen bonds. (*b*) Two aromatic protein side chains, Phe16 and Trp183, 'stack' on the non-polar faces of the carbohydrate.

This pattern is thought to be a result, in part, of the entropic cost of fixing a freely rotating protein hydroxyl group while simultaneously fixing the ligand hydroxyl group. Amides and carbonyls are usually fixed in a planar geometry and thus do not require as much energy to compensate for their loss of entropy in ligand binding.

The vicinal hydroxyl groups of carbohydrates provide an ideal geometry for the formation of 'bidentate' hydrogen bonds, where the pair of hydroxyls interacts with two functional groups of a single amino-acid side chain or the main-chain amide groups of two consecutive residues (Fig. 23.3.2.1). These interactions occur when the adjacent carbohydrate hydroxyls are either both equatorial, or one is equatorial and the other axial. The inter atomic distance for the carbohydrate hydroxyl oxygens is ~2.8 Å in these cases, allowing for a bidentate interaction with the planar side chains of aspartate, asparagine, glutamate, glutamine and arginine. Bidentate hydrogen bonds have not been observed for consecutive axial hydroxyls where the oxygen–oxygen distance increases to ~3.7 Å.

Carbohydrates often present a disc-like face of non-polar aliphatic hydrogen atoms which proteins recognize through the use of aromatic side chains. The protein aromatic groups are 'stacked' on the flat face of the carbohydrate, thus generating both specificity and binding energy through van der Waals interactions. Tryptophan, the aromatic amino acid with the largest surface area and highest electronegativity, is the most common side chain employed in van der Waals 'stacking' with carbohydrates. The infrequent use of aliphatic groups in the binding of the non-polar carbohydrate faces suggests that the aromatic moieties are employed in a specific manner. The electron-rich electron clouds of the aromatic side chains may provide a strong electrostatic interaction with the aliphatic carbohydrate protons that could not be satisfied by protein aliphatic groups. The anionic character of aromatic side chains is observed in a number of protein–intramolecular (Chapter 22.3) and protein–ligand interactions (see below).

23.3.3. Metals

Metal ions provide a number of important functions in their diverse and ubiquitous interactions with proteins. The most common function for a protein-bound metal ion is the stabilization and orientation of the protein tertiary structure through coordination to specific protein functional groups. In addition to this structural role, metal ions are also often directly involved in enzyme catalysis and protein function. Examples of these functions include redox reactions, the activation of chemical bonds and the binding of specific ligands. Myoglobin, the first protein structure determined by X-ray crystallography, specifically binds molecular oxygen through an iron ion of a haem cofactor. Myoglobin provides a prototypic example of a protein and a metal ion providing a unique and specific functionality through their combination.

23.3.3.1. Metals important in protein function and structure

A number of metals are relatively abundant and available in living systems (Table 23.3.3.1) (Glusker, 1991). The most common ions include sodium, potassium, magnesium and calcium. Along with these ions, a large variety of trace metals are also found coordinated to proteins. The structures of protein complexes with some of these trace ions, including iron, zinc and copper, have been studied extensively for some time (Glusker, 1991). More recently, the structures of protein complexes with more unusual ions, such as nickel, vanadium and tungsten, have been determined (Volbeda *et al.*, 1996).

Specificity in the interactions between proteins and metal ions is conferred through each ion's preference for the coordinating atoms and the geometry of the binding site. All four of the more common metals, *i.e.* sodium, potassium, magnesium and calcium, are classified as 'hard' metals, referring to the polarizability of the

Table 23.3.3.1
Metal ions associated with proteins

Metal ion	Concentration in blood plasma (m*M*)	Common cofactors	Hard/soft classification	Common coordination number and geometry	Preferred ligand atom
Na^+	138		Hard	6	O
K^+	4		Hard	8	O
Ca^{2+}	3		Hard	8	O
Mg^{2+}	1		Hard	6	O
Fe	0.02	Haem	Intermediate	6 (octahedral)	N
Zn^{2+}	0.02		Intermediate	4 (tetrahedral), 6 (octahedral)	N, S
Cu^{2+}	0.015		Soft	4 (tetrahedral)	S

W	0	Pterin	Intermediate	6 (octahedral)	S
V	0			5 (trigonal bipyramidal)	

electron cloud of the ion. The nucleus of a hard metal has a relatively tight hold on the surrounding electrons. These ions lack easily excitable unshared electrons and have a low polarizability. The interactions between these metals and their ligands tend to have the character of ionic interactions rather than the more covalent nature preferred by the 'soft' metals. In general, the hard metals prefer to coordinate with hard acids, such as the oxygen atoms of hydroxyls, carbonyls and carboxyls.

The soft metals have a high polarizability, large ionic radius and several unshared valence electrons. They generally prefer to coordinate with soft acids, such as the thiol and thiol ether groups of cysteine and methionine. The loosely held valence electrons of soft metals tend to favour partially covalent π-bonding with their coordinated ligands. These outer-shell electrons can be donated to the empty outer orbitals of the ligand atom. The partially covalent nature of these bonds yields more stable complexes than the ionic complexes of the hard metals. This partial covalent bond also polarizes the ligand coordinated to the metal and can thus activate adjacent atoms to nucleophilic attack.

A large number of the transition metals, including zinc and iron, form ions that have intermediate polarizability with regard to hard and soft metals. These ions mainly prefer nitrogen ligands like the imidazole side chain of histidine or the central nitrogens of the haem cofactor.

The geometry of the metal-binding site in a protein depends on a combination of the radial size of the ion as well as the polarizability of the metal. The number of coordinating ligands around the metal is primarily correlated with the relative size of the ion, where as many anions as possible are packed around the cationic metal without leaving any cavities (Orgel, 1966). This leads to a relatively simple correlation between the ratio of the radii of the cation and the anion ($r_{\rm cation}/r_{\rm anion}$) with the coordination number. Beyond this simple geometric constraint, the coordination number is also influenced by the repulsion between the closely packed anion ligands. This repulsion can be tempered by the distortions in the cation's electron cloud, leading to a dependency between the coordination number and the polarizability of the metal ion. Table 23.3.3.1 gives the most common coordination numbers and geometries for the listed metal ions. For a more comprehensive description of possible coordination geometries, see Glusker (1991).

A short example of the diversity of metal functions in protein complexes is found in a comparison between the calcium-binding proteins calmodulin and staphyloccocal nuclease. Calmodulin functions in signal transduction by binding to a wide variety of proteins in a calcium-dependent manner. In the absence of calcium, calmodulin adopts a conformation where two loosely folded domains are connected by a flexible α-helix analogous to two balls tied together by a string. In the presence of Ca^{2+}, each of the two domains of calmodulin binds to a single metal ion. The binding of Ca^{2+} to the two calmodulin domains induces a large conformational change in the protein, which confers a high affinity for peptide ligands. Crystallographic studies show that the two calcium-bound domains form a clamp that closes on the target peptide ligand (Meador *et al.*, 1995). Thus, in this case, the metal ion plays an indirect role as a structural element in the protein function.

In the case of staphylococcal nuclease, calcium binding appears to play a more direct role in the catalytic function of the protein. A Ca^{2+} ion binds at the active site and coordinates with protein side chains, water molecules and the substrate phosphate group. The addition of calcium affects the nuclease reaction both in the binding of the substrate and directly in the catalytic step. Although calcium increases the K_m of the nucleic acid substrate, this effect can be reproduced with a large number of other metal ions (Tucker *et al.*, 1979). The effect on catalysis, however, is specific to Ca^{2+} ions. In a proposed mechanism, Ca^{2+} directly contributes to catalysis by activating a water-derived hydroxide ion for nucleophilic attack on the phosphorus atom of the nucleic acid backbone (Cotton *et al.*, 1979).

23.3.4. Protein–nucleic acid interactions

23.3.4.1. The DNA double helix

DNA provides one of the more compelling protein 'ligands' for biophysical study, as the sequence-specific binding of proteins to the DNA double helix mediates the interaction between the environment surrounding the living cell and the information 'programmed' into the cell within its genome. A classic example of such a process is the response of the bacteria *Escherichia coli* to the nutrients in the surrounding media through the regulation of gene expression. A simple case of this interaction is found in the biosynthesis of the amino acid tryptophan. The transcription of the genes necessary for the synthesis of tryptophan is suppressed when tryptophan is present in the environment. This process is mediated by the tryptophan-dependent sequence-specific binding of the trp repressor protein to the *trp* operon within the genes encoding the metabolic enzymes (Joachimiak *et al.*, 1983). In the absence of tryptophan, the affinity of the aporepressor for the *trp* operon is dramatically reduced. Thus, when tryptophan is not available in the environment, transcription of the biosynthetic genes proceeds. In mammalian cells, the analogous process is observed in the activation of gene expression through hormones, cytokines and other stimuli.

Although DNA has often been considered to be a long, nearly featureless cylindrical double helix, proteins have evolved with exquisite specificity for their cognate DNA sequences. This apparent contradiction can be reconciled with the acknowledgement of two recently appreciated properties of DNA (Harrington & Winicov, 1994). First, the local structure of DNA is actually highly variable and dependent on the specific sequence of the base pairs in the helical ladder. Second, the DNA double helix is a relatively soft structure that is easily deformed into concerted bends, kinks and other distortions. DNA-binding proteins thus recognize their cognate sequences both by utilizing the unique local structure of the double helix and by inducing distortions into the helix which facilitate recognition.

The most intuitive features of the double helix that are important in sequence-specific recognition are the unique surfaces presented by the bases in the helix grooves. DNA is primarily found in a B-form helix that presents a wide, accessible major groove and a deep, narrow minor groove. An analysis of the arrangement of hydrogen-bonding functional groups presented by DNA bases (Fig. 23.3.4.1) suggests that the sequence-specific recognition of the DNA helix is best facilitated through the major groove, where each of the four possible base-pair combinations present unique hydrogen-bonding patterns (Steitz, 1990). The majority of sequence-specific DNA-binding proteins of known structure appear to utilize this direct readout of the major groove by inserting a portion of an α-helix, a two-stranded β-hairpin, or even a peptide coil which presents complementary hydrogen-bonding arrangements with the DNA bases (Pabo & Sauer, 1992; Steitz, 1990). The narrow surface of the minor groove presents some characteristic hydrogen-bonding patterns: however, the absolute identity of each base pair is

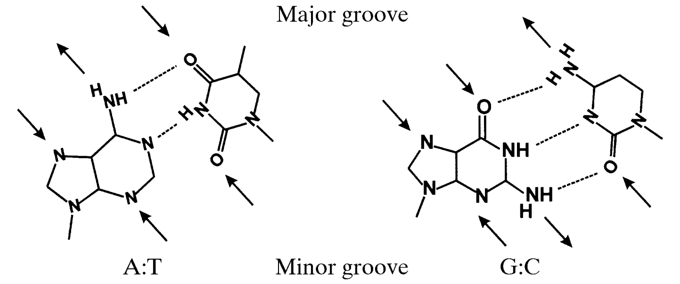

Figure 23.3.4.1
A schematic diagram of the base pairs of DNA showing the hydrogen-bonding groups which may be used in the sequence-specific recognition of DNA. The major groove is at the top of the figure and the minor groove at the bottom. Arrows point towards hydrogen-bond acceptors and away from donors.

ambiguously represented in these patterns (Fig. 23.3.4.1). The similar position of hydrogen-bonding groups in the minor groove would make it hard to distinguish AT base pairs from TA base pairs and GC base pairs from CG base pairs. Although there are proteins that recognize DNA through the minor groove, such as the TATA-box binding protein, the recognition of their target is completed through dramatic distortion of the DNA helix through intercalation (see below).

α-Helices are the most frequently observed structural motif for recognition in the major groove of DNA (Pabo & Sauer, 1992). The overall shape and dimensions of the α-helix are geometrically suited for binding in the major groove of a B-DNA helix (Fig. 23.3.4.2). The exact orientations of helices in various protein–DNA complexes are quite variable. Most helices bind in the major groove at an angle of approximately 30 (15)° from the plane normal to the DNA helical axis (Fig. 23.3.4.3). However, the numerous variants to this rule would include the trp repressor/operator complex, where only the N-terminal end of the 'recognition' helix is inserted into the major groove (Otwinowski *et al.*, 1988*a*,*b*). Interactions observed between these inserted elements and the DNA bases include the common direct hydrogen bond between the protein side chain and base, the less common hydrogen bond between the protein backbone and base, indirect but specific hydrogen bonding through water molecules, and hydrophobic interactions.

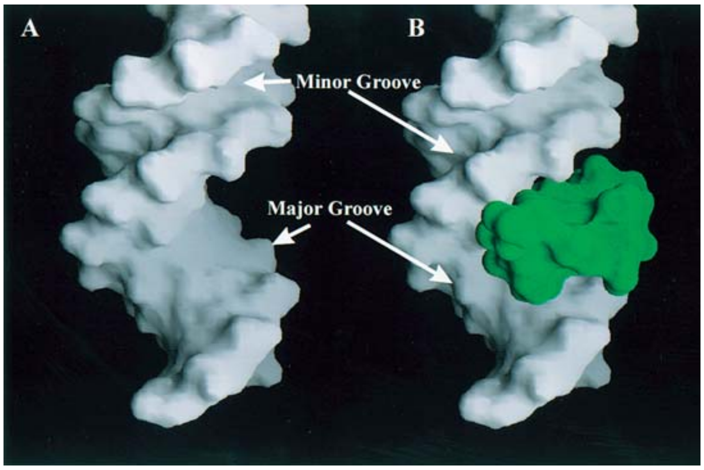

Figure 23.3.4.2
(*a*) A space-filling model of B-DNA showing the relative accessibility of the major and minor grooves. (*b*) A helix of the 434 repressor bound in the major groove of the helix, illustrating how the dimensions of a protein α-helix are compatible for reading the major groove of B-DNA (Shimon & Harrison, 1993).

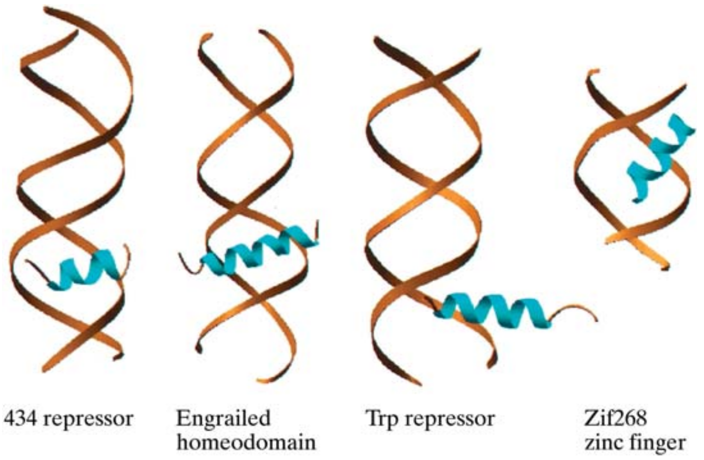

Figure 23.3.4.3
A comparison of the orientations of α-helices bound in the major groove, taking examples from four DNA-binding proteins: the 434 repressor (Shimon & Harrison, 1993), the engrailed homeodomain (Kissinger *et al.*, 1990), the trp repressor (Otwinowski *et al.*, 1988*a*,*b*) and the Zif268 zinc finger (Pavletich & Pabo, 1991). The DNA backbone is shown as a brown ribbon, whereas the protein helix is shown as a blue ribbon.

There appears to be no simple correlation between the primary sequence of the peptide segments which make specific base contacts and the DNA sequence that those segments recognize (Pabo & Sauer, 1992; Steitz, 1990). Examples of every polar protein side chain participating in specific hydrogen bonds with DNA bases have been observed, but each amino acid does not show any preference for any one particular base. What is observed is that conserved residues within families of DNA-binding proteins tend to make conserved base-specific interactions in DNA–protein complexes. Strikingly, this subset of interactions which are conserved within protein families include cooperative hydrogen bonding reminiscent of the pairs of hydrogen bonds often observed in carbohydrate–protein complexes. These interactions, which include the pairing of arginine with guanine and glutamine or asparagine with adenine, were predicted early on by Seeman *et al.* (1976).

Although the elements of protein structure in direct contact with the DNA bases play a prominent role in sequence specificity, these elements are not sufficient to impart the specificity of the DNA-binding protein. This statement is supported by the variety of orientations in which the 'recognition' helices bind to the major groove. The structural context of the recognition elements and the overall docking of the protein to the DNA helix play as important a role in specificity as the direct base interactions.

The contacts between the protein and the ribose–phosphate backbone of the DNA appear to be one of the more important aspects of the 'indirect readout' of the DNA sequence (Pabo & Sauer, 1992). On average, more than half of the interactions between protein and DNA in complex structures involve the backbone of the DNA helix. Thus, the sheer number of interactions suggests that these contacts serve an important function in recognition. Although several of the protein–DNA-backbone contacts observed involve salt bridges between the phosphates and basic protein side chains, these interactions are not as highly represented as one might expect. This could be a result of the high degree of flexibility inherent in the long side chains of arginine and lysine. Instead, examples of every basic and neutral residue and occasionally even acidic residue with some hydrogen-bonding potential interacting with the phosphate backbone have been observed. These contacts may contribute to specificity through two mechanisms. First, they can establish the exact orientation of the base-specific contacts relative to the 'rungs' in the phosphate backbone. Second, they may read the base sequence indirectly through sequence-specific backbone distortions or flexibility. There are numerous examples of DNA–protein complexes with highly distorted DNA helices. There is also evidence that certain DNA sequences inherently confer bends within the B-form helix. Thus, it is conceivable that protein interactions with the DNA backbone may confer specificity by selecting for a specific distorted conformation of the helix.

The most dramatic distortion of the DNA helix has been observed in DNA–protein complexes where the protein induces a kink or bend through the intercalation of the DNA helix at the minor groove (Werner *et al.*, 1996*a*,*b*). Intercalation involves the insertion of a hydrophobic protein side chain into the helix, disrupting the stacking of two adjacent base pairs, and, in some cases, the side chain itself then stacks with one of the base pairs. Examples of this mode of binding include the complexes of the TATA-box binding protein (TBP), the PurR repressor and the human oncogene *ETS1* with their cognate DNA partners (Werner *et al.*, 1996*a*,*b*). The *ETS1*–DNA complex provides the only current example of complete intercalation of the DNA extending from the minor groove to the major groove. A tryptophan side chain extends into the helix from the minor groove and stacks with one of the displaced base pairs. The remaining base pair contacts the ring system of the tryptophan edge in forming a pseudo-hydrogen bond between the indole hydrogens and the π-rings of the DNA bases. In *ETS1*, the deformation of the DNA helix resulting from protein intercalation results in the kinking of the helical axis from 45° to about 60°.

Examples of protein intercalation of the DNA helix from the major groove are found in proteins, such as the methyltransferases, that perform chemistry on the bases of the DNA. To perform their enzymatic function, these proteins must extract the target base from the DNA helix and 'flip' the base out into the enzyme active site (Cheng, 1995). The resulting void in the DNA is then filled by protein side chains that partially satisfy the hydrogen-bonding and van der Waals interactions that were broken when the target base was flipped. Although there are only a few known structures of DNA–protein complexes with extrahelical bases, base flipping is thought to be a relatively common feature of DNA-modifying enzymes.

23.3.4.2. *Single-stranded sequence-nonspecific DNA–protein interactions*

There have been a few reports of single-stranded DNA–protein complex structures, all of which involve the sequence-nonspecific recognition of DNA. In the binding of a tetranucleotide to the exonuclease active site of the DNA polymerase I Klenow fragment (Freemont *et al.*, 1988), extensive hydrogen-bonding interactions between the sugar–phosphate backbone and the protein are observed. This provides the most intuitive mechanism for sequence-nonspecific nucleic acid binding, where the protein simply recognizes the phosphate backbone of a single-stranded coil. The protein also appears to form a few hydrophobic interactions with the DNA bases; however, these interactions, which include the partial intercalation between two bases, are thought to be nonspecific.

The structure of replication protein A complexed with single-stranded DNA does not exhibit the intuitive nonspecific mechanism of recognition found in the Klenow fragment (Bochkarev *et al.*, 1997). In this structure, the DNA is extended with its bases splayed out over the surface of the protein. The bases form several pairwise stacking interactions that are interrupted by intercalating protein side chains. Contrary to the sequence-nonspecific nature of recognition, numerous hydrogen bonds are found between the protein and the bases of the DNA strand. These base-dependent contacts require that the protein–DNA interactions must be flexible and plastic in order to accommodate different base sequences.

23.3.4.3. *RNA*

Although RNA and DNA are chemically similar, RNA presents a much greater variety of shapes and surfaces compared to the relatively simple B-form helix of DNA. Generally single-stranded, RNA often forms secondary structuresdriven by the base pairing of complementary stretches of sequence within the same strand. The formation of base-paired regions can result in stem loops, bulges and helices which can further assemble into more complicated tertiary structures, such as that observed for transfer RNAs. Protein-mediated recognition of RNA often depends as much on the three-dimensional structure presented by these secondary structures as on the specific identity of the base sequence.

Very little information is currently available on the structural details of protein–RNA interactions (Nagai, 1996). Only a handful of protein–RNA complex structures have been determined. These fall into three basic categories, depending on the secondary structure of the RNA: four tRNA–protein complexes, two stem-loop–protein complexes and a capped single-stranded RNA–protein complex.

23.3.4.4. *Transfer RNA*

In the four known structures of tRNA bound to their aminoacyl tRNA synthetases (Cusack *et al.*, 1996*a*,*b*; Goldgur *et al.*, 1997; Rould *et al.*, 1991), the effects of RNA's preference for A-form helices on recognition are immediately apparent. The proteins make numerous contacts in the shallow and exposed minor grooves of the RNA helices. This contrasts with the extensive use of the major groove in the recognition of B-form DNA helices. Beyond this generalization, the details of tRNA recognition differ in each specific case. Comparison of the protein-bound tRNA to the structure of free tRNA reveals that the proteins tend to distort the RNA conformation and partially unwind the helices near the anti-codon loop. In one case, namely the structure of glutamyl-tRNA synthetase (Rould *et al.*, 1991), the final base pair near the acceptor stem of the tRNA is broken, and the CCA acceptor makes a dramatic hairpin turn into the enzyme active site.

23.3.4.5. *Stem loops*

One fascinating observation in viewing the structures of RNA-binding proteins, even in the absence of RNA, is that aside from the tRNA-binding synthetases, they all appear to have evolved from or towards a very similar general fold (Burd & Dreyfuss, 1994). This fold, exemplified by the RNP domain found in numerous RNA-binding proteins, consists of a β-sheet surrounded on one side by α-helices and solvent-exposed on the opposing face. This general folding architecture is found in RNP domains, ribosome proteins, K-homologous domains (KH), double-stranded RNA-binding domains and cold shock proteins. Although each of these subsets of RNA-binding domains has a different topology and most probably bind to RNA with different surfaces, they all appear to have this alpha–beta–solvent architecture.

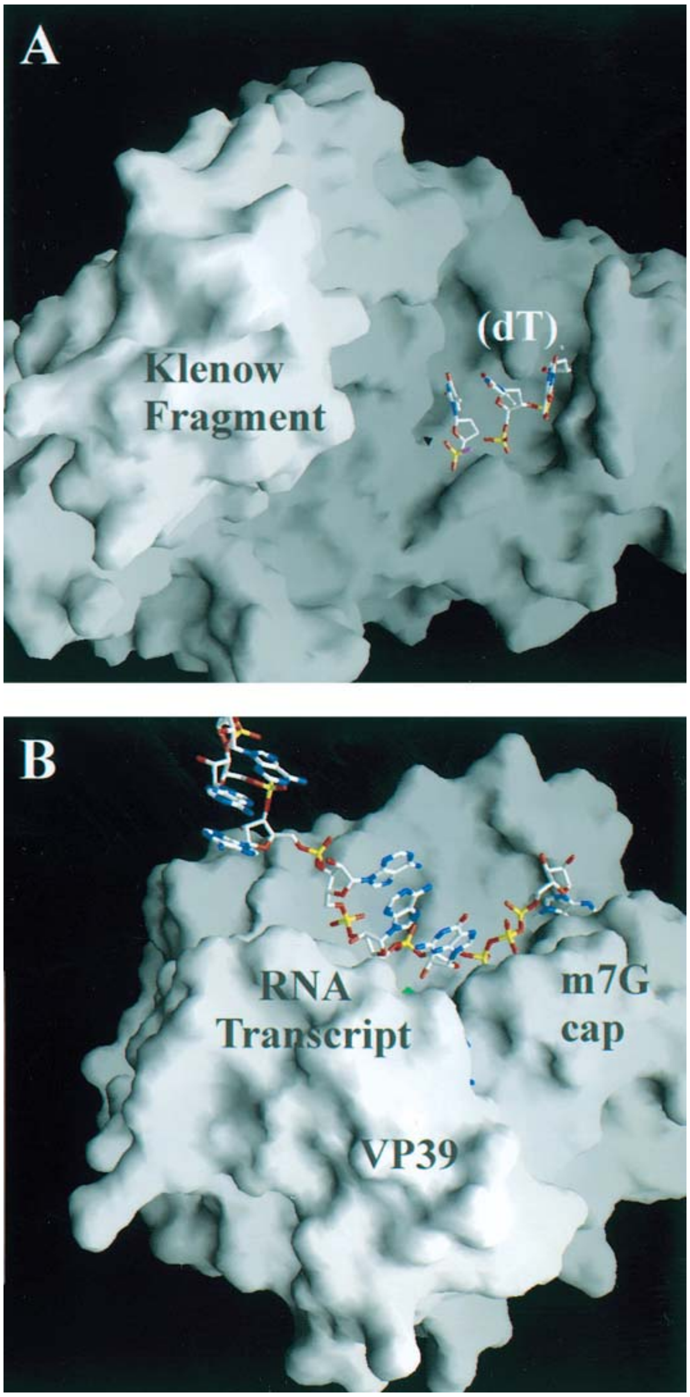

Figure 23.3.4.4
The sequence-nonspecific recognition of single-stranded nucleic acid. (*a*) Oligo(dT) bound in the exonuclease active site of DNA polymerase I Klenow fragment (Freemont *et al.*, 1988). (*b*) A short capped RNA transcript bound to the VP39 RNA methyltransferase (Hodel *et al.*, 1998). Both proteins primarily interact with the backbone of the nucleic acid.

Two proteins with this architecture have been co-crystallized with their specific RNA stem-loop ligands (Nagai *et al.*, 1995; van den Worm *et al.*, 1998). In both cases, the loop of the RNA binds to the open face of the β-sheet where solvent-exposed aromatic amino-acid side chains stack with the extrahelical bases of the RNA. Unpaired bases from the RNA also form numerous specific hydrogen bonds with protein side chains and polar backbone groups, imparting sequence specificity in the interaction. These structures suggest that the flat, open face of a β-sheet provides a good surface for RNA binding, where the extrahelical bases can make extensive and specific contacts with the protein.

23.3.4.6. Single-stranded sequence-nonspecific RNA–protein interactions

There is a single example of a single-stranded RNA–protein complex which is sequence-nonspecific. The structure of the vaccinia RNA methyltransferase VP39 bound to a 5′m^{7}G-capped RNA hexamer reveals a mechanism of nonspecific recognition reminiscent of the Klenow fragment–DNA tetramer complex (Hodel *et al.*, 1998). The RNA forms two short single-stranded helices of three bases each. The first of these helices binds in the active site of VP39 solely through hydrogen bonds between the protein and the ribose–phosphate backbone. The bases of the RNA strand stack together as trimers, but do not form any interactions with the protein (Fig. 23.3.4.4). Like the Klenow–DNA complex, this observation suggests an intuitive mechanism for sequence-nonspecific nucleic acid binding, where the single-stranded RNA forms short transient helices driven by intramolecular stacking interactions. The protein then recognizes and stabilizes the helical backbone conformation formed by this transient stacking without interacting with the bases themselves.

23.3.4.7. The recognition of alkylated bases

The complex of VP39 with capped RNA also illustrates a final example of the diversity of protein–ligand interactions in the specific recognition of the 7-methylguanosine cap. When guanosine is methylated at the N7 position, a positive charge is introduced to the π-ring system of the base. Eukaryotic cells utilize the methylation of a guanosine base at the N7 position as a tag or cap for the 5′ end of messenger RNA. The m^{7}G5′ppp mRNA cap is specifically recognized in the splicing of the first intron in nascent transcripts, in the transport of mRNA through the nuclear envelope and in the translation of the message by the ribosome (Varani, 1997). Two structures of specific m^{7}G binding proteins are now known: VP39 and the ribosomal cap-binding protein IF-4E (Hodel *et al.*, 1997; Marcotrigiano *et al.*, 1997). Each structure offers clues as to how the proteins can discriminate between the charged methylated m^{7}G base and the unmodified guanosine base. The m^{7}G base is stacked between aromatic protein side chains and hydrogen bonded to acidic protein residues (Fig. 23.3.4.5). One long-held hypothesis is that IF-4E, with dual tryptophan residues, binds specifically to the positively charged form of the base through a charge-transfer complex (Ueda, Iyo, Doi, Inoue & Ishida, 1991). The formation of a charge-transfer complex is evident in small-molecule studies and spectroscopic studies with IF-4E (Ueda, Iyo, Doi, Inoue, Ishida *et al.*, 1991). However, VP39 performs the same discrimination with the much less electronegative phenylalanine and tyrosine side chains (Hodel *et al.*, 1997). So far, no charge-transfer complex has been observed in VP39.

The recognition of charged methylated bases is important not only in mRNA processing, but also in the repair and recognition of DNA damaged by alkylating carcinogens. The mechanism by which the charged m^{7}G base is recognized is probably similar to how other positively charged bases, such as 3-methyladenosine, O2-methylcytosine and O2-methylthymidine, are recognized. In fact, the *E. coli* DNA repair enzyme, AlkA, will catalyse the glycolysis of all of these bases (Lindahl, 1982). The structure of AlkA is known, but only in the absence of a substrate (Labahn *et al.*, 1996). In this structure, a number of solvent-exposed tryptophan residues are found at the putative active site. This observation suggests that AlkA may recognize positively charged bases through an aromatic ‘sandwich’, much like that found in IF-4E and VP39.

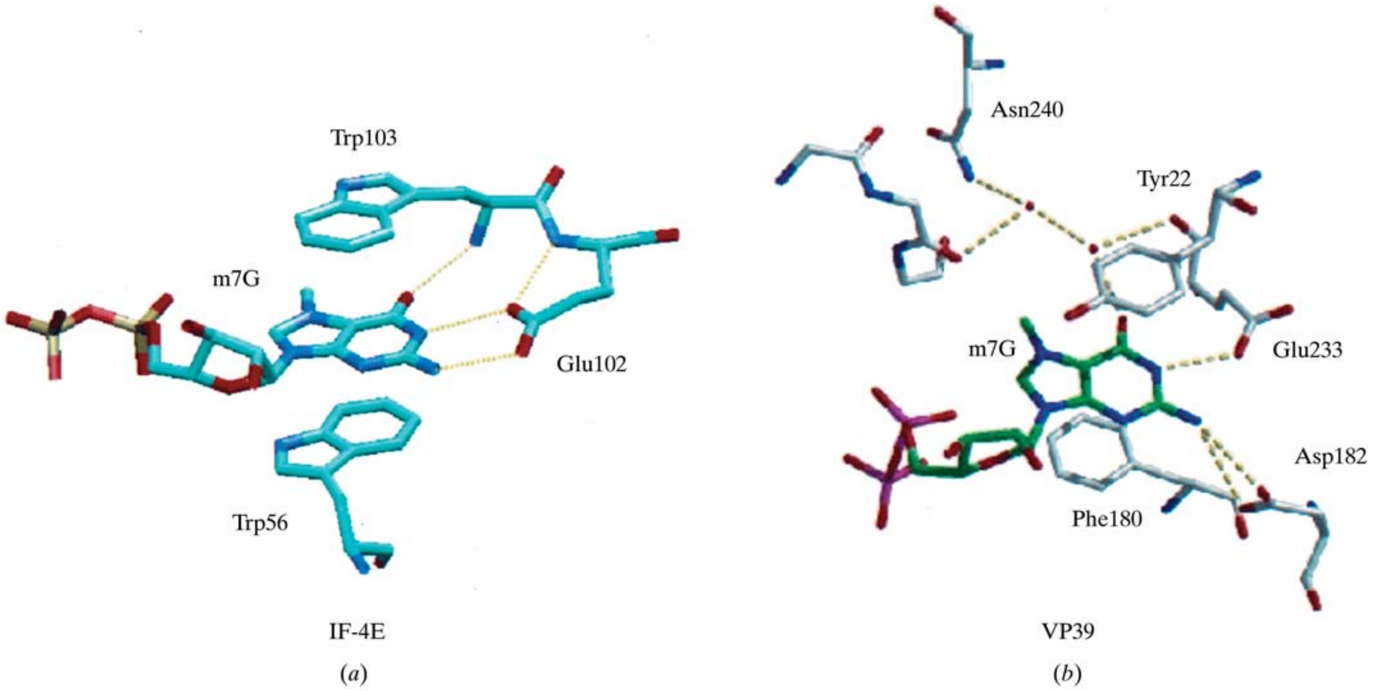

Figure 23.3.4.5
The specific recognition of the messenger RNA 7-methylguanosine cap. (*a*) The residues contacting the m^7G base in the cap-binding protein, IF-4E (Marcotrigiano *et al.*, 1997). (*b*) The residues interacting with the cap in the vaccinia RNA methyltransferase VP39 (Hodel *et al.*, 1997). Both proteins bind to the charged, methylated base by stacking aromatic amino acids on both sides of the base.

23.3.5. Phosphate and sulfate

Novel features of molecular recognition and electrostatic interactions of these two tetrahedral oxyanions have emerged from our crystallographic and functional studies of the phosphate-binding protein (PBP) and sulfate-binding protein (SBP), which serve as extremely specific initial receptors for ATP-binding cassette (ABC)-type active transport or permease in bacterial cells. The complexes of these proteins have K_d values in the low μM range. Although phosphate and sulfate are structurally similar, at physiological pH PBP and SBP exhibit no overlap in specificity (Medveczky & Rosenberg, 1971; Pardee, 1966; Jacobson & Quiocho, 1988). This stringent specificity prevents one tetrahedral oxyanion nutrient from becoming an inhibitor of transport for the other. The specificity of the PBP-dependent phosphate transport system is also shared by other phosphate transport systems in eukaryotic cells and across brush borders and into mitochondria.

As described below, discrimination between anions is based solely on the protonation state of the ligand. Sulfate, a conjugate base of a strong acid, is completely ionized at pH values above 3, whereas phosphate, a conjugate base of a weak acid, remains protonated up to pH 13.

The structure of the PBP–phosphate complex was initially determined at 1.7 Å resolution (Luecke & Quiocho, 1990). The resolution has been pushed to an ultra high resolution of 0.98 Å, the first reported for a protein with a molecular weight as high as 34 kDa with a bound ligand (Wang *et al.*, 1997). The bound phosphate is completely desolvated and sequestered in the protein cleft between two domains. It makes 12 hydrogen bonds with the proteins (11 with donor groups and one with an acceptor group), as well as one salt link to an Arg that is in turn salt-linked to an Asp residue (Fig. 23.3.5.1). The distances of the 12 hydrogen bonds between phosphate and PBP obtained from the ultra high resolution structure range from 2.432 to 2.906 Å (Wang *et al.*, 1997). The Asp56 carboxylate, the lone acceptor group, plays two key roles in conferring the exquisite specificity of PBP. It recognizes, by way of the hydrogen bond, a proton on the phosphate and presumably disallows, by charge repulsion, the binding of a fully ionized sulfate dianion (Luecke & Quiocho, 1990).

The SBP binding-site cleft is also tailor-made for sulfate (Pflugrath & Quiocho, 1985). In keeping with the stringent specificity of SBP for fully ionized tetrahedral oxyanions (Pardee, 1966; Jacobson & Quiocho, 1988), the bound sulfate, which is also completely dehydrated and buried, is held in place by seven hydrogen bonds made entirely with donor groups from uncharged polar residues of the protein (Fig. 23.3.5.2) (Pflugrath & Quiocho, 1985). The absence of a hydrogen-bond acceptor group accounts for the inability of SBP to bind phosphate. Interestingly, the absence of a salt link and the formation of five fewer hydrogen bonds with the bound sulfate (Fig. 23.3.5.2*b*) than with the bound phosphate (Fig. 23.3.5.1*b*) do not make the affinity of the SBP–sulfate complex any weaker than that of the PBP–phosphate complex. In fact, the sulfate binds 10–20 times more tightly to SBP (Pardee, 1966; Jacobson & Quiocho, 1988). Also, the hydration energies of both anions are likely to be similar.

The ability of PBP and SBP to differentiate each oxyanion ligand through the presence or absence of proton(s) is an extremely high level of sophistication in molecular recognition. The importance of complete hydrogen bonding in recognition of buried ligands is powerfully demonstrated in PBP and SBP. As the sulfate is fully ionized (*i.e.* possesses no hydrogen at physiological pH), repulsion occurs at Asp56 of PBP specifically for this dianion. On the other hand, SBP is unable to bind phosphate because it contains no hydrogen-bond acceptor in the binding site. Significantly, despite the potential for a large number of matched hydrogen-bonding pairs, a single mismatched hydrogen bond (*e.g.* a fully ionized sulfate providing no proton for interaction with Asp56 of PBP and no acceptor group in SBP for a phosphate proton) represents a binding energy barrier of 6–7 kcal mol^{-1} (1 kcal mol^{-1} = 4.184 kJ mol^{-1}).

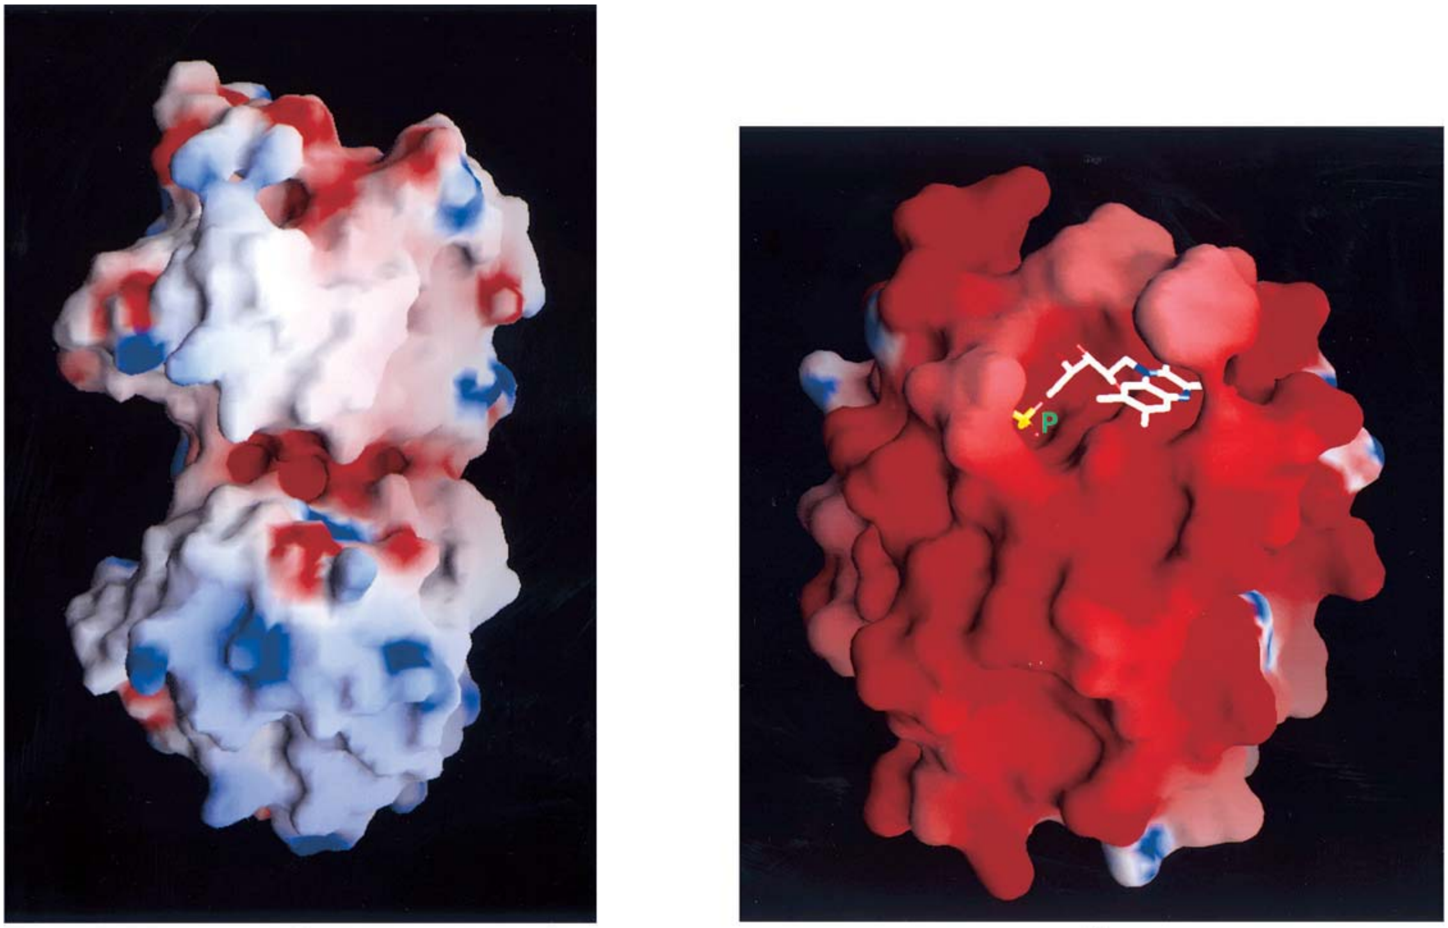
Figure 23.3.5.2
Seven hydrogen-bonding interactions between the sulfate-binding protein (SBP) and sulfate. (*a*) Interactions based on the 1.7 Å structure (J. Sack & F. A. Quiocho, unpublished data). (*b*) Schematic diagram of the interaction.

23.3.5.1. *Dominant role of local dipoles in stabilization of isolated charges*

A novel finding of further paramount importance and wide implication is how the isolated charges of the protein-bound phosphate and sulfate are stabilized. No counter-charged residues or cations are associated with the sulfate completely buried in SBP. Although a salt link involving Arg135 is formed with the phosphate bound to PBP, it is shared with an Asp residue (Fig. 23.3.5.1*b*). Moreover, site-directed mutagenesis studies indicate that phosphate binding is quite insensitive to modulation of the salt link (Yao *et al.*, 1996). These findings are a powerful demonstration of how a protein is able to stabilize the charges by means other than salt links. Experimental and computational studies indicate that local dipoles, including the hydrogen-bonding groups and the backbone NH groups from the first turn of helices, immediately surrounding the sulfate and phosphate are responsible for charge stabilization (Pflugrath & Quiocho, 1985; Quiocho *et al.*, 1987; Åqvist *et al.*, 1991; He & Quiocho, 1993; Yao *et al.*, 1996; Ledvina *et al.*, 1996). Helix macrodipoles play little or no role in charge stabilization of the anions. The same principle of charge stabilization by local dipoles also applies for the following buried uncompensated ionic groups: Arg151 of the arabinose-binding protein (Quiocho *et al.*, 1987), the zwitterionic leucine ligand bound to the leucine/isoleucine/valine-binding protein (Quiocho *et al.*, 1987), the potassium in the pore of the potassium channel (Doyle *et al.*, 1998) and Arg56 of synaptobrevin-II in a SNARE complex (Sutton *et al.*, 1998).



(*a*) (*b*)

Figure 23.3.5.3
Electrostatic surface potential of (*a*) the phosphate-binding protein and (*b*) flavodoxin. The molecular surface electrostatic potentials, calculated and displayed using *GRASP* (Nicholls *et al.*, 1991), are −10 kT (red), neutral (white) and +10 kT (blue) [see Ledvina *et al.* (1996) for more details]. (*a*) Wild-type phosphate-binding protein based on the X-ray structure of the open cleft, unliganded form (Ledvina *et al.*, 1996). The phosphate-binding site is located in the cleft (with negative surface potential) in the middle of the molecule and between the two domains. (*b*) Flavodoxin with bound flavin mononucleotide (FMN). The phosphoryl group (P) of the FMN is bound in a pocket with intense negatively charge surface potential. The surface potential was calculated without the bound flavin mononucleotide using the structure from the Protein Data Bank (PDB code: 2fox).

23.3.5.2. Short hydrogen bonds

The ultra high resolution refined structure of the PBP–phosphate complex is the first to show structurally the formation of an extremely short hydrogen bond (2.432 Å) between the Asp56 carboxylate of PBP and phosphate. Although this short hydrogen bond is within the proposed range of low-barrier hydrogen bonds with estimated energies of 12–24 kcal mol^{-1} (Hibbert & Emsley, 1990), its contribution to phosphate binding affinity has been assessed to be no better than that of a normal hydrogen bond (Wang *et al.*, 1997). Thus, a unique role for short hydrogen bonds in biological systems, such as in enzyme catalysis (Gerlt & Gassman, 1993; Cleland & Kreevoy, 1994), remains controversial.

23.3.5.3. Non-complementary negative electrostatic surface potential of protein sites specific for anions

The presence of an uncompensated negatively charged Asp56 is unusual for an anion-binding site, as observed in PBP. In fact, a related discovery of profound ramification is that the binding-cleft region of PBP has an intense negative electrostatic surface potential (Fig. 23.3.5.3*a*) (Ledvina *et al.*, 1996). Non-complementarity between the surface potential of a binding region and an anion ligand is not unique to PBP. We have reported similar findings for SBP, a DNA-binding protein, and, even more dramatically, for the redox protein flavodoxin (Fig. 23.3.5.3*b*) (Ledvina *et al.*, 1996). Evidently, for proteins such as these, which rely on hydrogen-bonding interactions with only uncharged polar residues for anion binding and electrostatic balance, a non-complementary surface potential is not a barrier to binding. This conclusion is supported by very recent fast kinetic studies of binding of phosphate to PBP and the effect of ionic strength on binding (Ledvina *et al.*, 1998).

FAQ is an HHMI Investigator. The work carried out in his laboratory is supported in part by grants from NIH and the Welch Foundation.

Chapter 23.4. Nucleic acids

R. E. Dickerson

23.4.1. Introduction

In 1953, James Watson and Francis Crick solved the structure of double-helical DNA (Watson & Crick, 1953; Crick & Watson, 1954). So what has a dedicated cadre of X-ray crystallographers been doing for the subsequent 45 years? That is the subject of this chapter: the advance of our knowledge of nucleic acid duplexes, primarily from single-crystal X-ray diffraction, and the biological implications of this new knowledge. The focus will be primarily on DNA because much more is known about it, but DNA/RNA hybrids and duplex RNA will also be considered. Because the emphasis is on the geometry of the nucleic acid double helix, exotic structures, such as quadruplexes, hammerhead ribozymes and aptamers, will be omitted, as will larger-scale structures such as tRNA.

Fibre diffraction showed that there were two basic forms of DNA duplex: the common B form and a more highly crystalline A form (Fig. 23.4.1.1) that, in some but not all sequences, could be produced by dehydrating the fibre (Franklin & Gosling, 1953; Langridge *et al.*, 1960; Arnott, 1970; Leslie *et al.*, 1980). A- and B-DNA are contrasted in Figs. 23.4.1.2 and 23.4.1.3. The high-humidity B form has base pairs sitting squarely on the helix axis and roughly perpendicular to that axis. In contrast, in the low-humidity A form, the base pairs are displaced off the helix axis by *ca* 4 Å and are inclined 10–20° away from perpendicularity to that axis. The two grooves in B-DNA are of comparable depth because base pairs sit *on* the helix axis, but the major groove is wider than the minor because of asymmetry of attachment of base pairs to the backbone chains. In A-DNA, the minor groove is broad and shallow, whereas the major groove is cavernously deep (all the way from the surface of the helix, to the helix axis, and beyond) but can be quite narrow.

Pohl and co-workers had shown in the 1970s that alternating poly(dC-dG) is special in that it undergoes a reversible salt- or alcohol-induced conformation change (Pohl & Jovin, 1972; Pohl, 1976). Hence, it was not surprising that when DNA synthesis methods advanced to the stage where oligonucleotide crystallization became feasible, two separate research groups – those of Alexander Rich at MIT and Richard Dickerson at Caltech – elected to synthesize, crystallize and solve a short, alternating C-G oligomer. The result was a third family of DNA duplexes, Z-DNA (Fig. 23.4.1.4), first as the hexamer C-G-C-G-C-G (Z1) and then the tetramer C-G-C-G (Z3). (References to A-, B- and Z-DNA structures are listed at the end of Tables A23.4.1.1, A23.4.1.2 and A23.4.1.3 in the Appendix, respectively. They are cited by numbers beginning with A, B or Z.) Single-crystal analyses of the traditional helix types soon followed: B-DNA as C-G-C-G-A-A-T-T-C-G-C-G (B1), and A-DNA as both C-C-G-G (A1) and G-G-T-A-T-A-C-C (A2).

23.4.2. Helix parameters

23.4.2.1. *Backbone geometry*

Before making detailed comparisons of the three helix types, one must define the parameters by which the helices are characterized. The fundamental feature of all varieties of nucleic acid double helices is two antiparallel sugar–phosphate backbone chains, bridged by paired bases like rungs in a ladder (Fig. 23.4.2.1). Using the convention that the positive direction of a backbone chain is from 5′ to 3′ within a nucleotide, the right-hand chain in Fig. 23.4.2.1 runs downward, while the left-hand chain runs upward. A- or B-DNA is then obtained by twisting the ladder into a right-handed helix. But Z-DNA cannot be obtained from Fig. 23.4.2.1 simply by giving it a left-handed twist; both backbone chains run in the wrong direction for Z-DNA. A more complex adjustment is required, and this will be addressed again later.

The conformation of the backbone chain along each nucleotide is described by six torsion angles, labelled α through ζ, as shown in Fig. 23.4.2.2. An earlier convention termed these same six angles as ω, φ, ψ, ψ', φ', ω' (Sundaralingam, 1975), but the alphabetical nomenclature is now generally employed. Torsion angles are defined in Fig. 23.4.2.3, which also shows three common configurations: *gauche*$^-$ (−60°), *trans* (180°) and *gauche*$^+$ (+60°). These three configurations are especially favoured with sp^3 hybridization or tetrahedral ligand geometry at the two ends of the bond in question, because their 'staggered' arrangement minimizes ligand–ligand interactions across the bond. An 'eclipsed' arrangement with ligands at −120°, 0° (*cis*), and 120° is unfavourable because it brings substituents at the two ends of the bond into opposition. Table 23.4.2.1 lists the mean values and standard deviations of all six main-chain torsion angles for A-, B- and Z-DNA, as recently observed in 96 oligonucleotide crystal structures (Schneider *et al.*, 1997).

23.4.2.2. *Sugar ring conformations*

The type of ligand–ligand clash just mentioned is an important element in ensuring that five-membered rings, such as ribose and deoxyribose, are not ordinarily planar, even though the internal bond angle of a regular pentagon, 108°, is close to the 109.5° of tetrahedral geometry. A stable compromise is for one of the four ring atoms to lie out of the plane defined by the other four, as in Fig. 23.4.2.4. This is termed an 'envelope' or E conformation, by

---

This chapter is dedicated to Irving Geis, who died on 22 July 1997 at the age of 88, just as the chapter was begun. Irv was a pioneer in the representation of protein and DNA structures, beginning with illustrations for *Scientific American* articles on myoglobin (Kendrew, 1961), lysozyme (Phillips, 1966), cytochrome *c* (Dickerson, 1972) and DNA (Dickerson, 1983). He was coauthor with the present writer of *Structure and Action of Proteins* (Dickerson & Geis, 1969) and two later textbooks (Dickerson & Geis, 1976, 1983) and contributed drawings and paintings to a great number of other books and articles, most notably Voet & Voet's *Biochemistry* (Voet & Voet, 1990, 1995), which is a veritable gallery of Irv's art. His meticulous and carefully thought-out diagrams and drawings of myoglobin and haemoglobins have never been matched. More information about his life, work and art may be found in three articles by the present author (Dickerson, 1997*a*,*b*,*c*). Irv saw his role as one of bringing an understanding of protein structure to life scientists and sometimes referred to himself half-humorously as 'the Andreas Vesalius of molecular anatomy'. In view of the formative influence that his art exerted on the first generation of protein crystallographers and molecular biologists, it is more appropriate to remember Irv as the Leonardo da Vinci of macromolecules. As of late 2000, nearly all of Irving Geis' work – paintings, drawings, illustrations and correspondence – is being preserved for study as the Geis Archives at the Howard Hughes Medical Institute, Washington DC.

Copyright © 2012 International Union of Crystallography

analogy with a four-cornered envelope having a flap at an angle. Intermediate ‘twist’ or T forms are also possible, in which two adjacent atoms sit on either side of the plane defined by the other three, but this discussion will focus on the simple envelope conformations. In most cases, the accuracy of a nucleic acid crystal structure determination is such that it would be difficult to distinguish clearly between a given E form and its flanking T forms. For this reason, most structure reports consider only the E alternatives.

A convenient and intuitive nomenclature is to name the conformation after the out-of-plane atom and then specify whether it is out of plane on the same side as the C5′ atom (*endo*) or the opposite side (*exo*). Ten such conformations exist: five *endo* and five *exo*. In Fig. 23.4.2.4 (top), pushing the C3′ atom of the C3′-*endo* conformation into the plane of the ring would tend to push C2′ below the ring, passing through a T state and creating a C2′-*exo* conformation. C2′ can, in turn, be returned to the ring plane if C1′ is pushed above the ring, forming C1′-*endo*, and so on, around the ring. In this way, a contiguous series of alternating *endo/exo* conformations is produced, as listed in Table 23.4.2.2.

This ten-conformation *endo/exo* cycle can be generalized to a continuous distribution of intermediate conformations, characterized by a pseudorotation angle, P (Altona *et al.*, 1968; Altona & Sundaralingam, 1972), with the ten *endo/exo* conformations spaced 36° apart (Table 23.4.2.2). Fig. 23.4.2.5 shows the calculated potential energy of conformations around the pseudorotation cycle (Levitt & Warshel, 1978). Note that C2′-*endo* and C3′-*endo* are most stable, that the pathway between them along the right half of the circle remains one of low energy, but that a large $6\,\text{kcal mol}^{-1}$ potential energy barrier ($1\,\text{kcal mol}^{-1} = 4.184\,\text{kJ mol}^{-1}$) effectively forbids conformations around the left half of the circle.

As Fig. 23.4.2.4 indicates, the main-chain torsion angle, δ, is sensitive to ring conformation, because the C5′—C4′ and C3′—O3′ bonds that define the angle shift as ring puckering changes. The idealized relationship between torsion angle, δ, and pseudorotation angle, P (Saenger, 1984), is

$$\delta = 40^\circ \cos(P + 144^\circ) + 120^\circ.$$

Fig. 23.4.2.6 shows the observed torsion angles, δ, and pseudorotation angles, P, from X-ray crystal structure analyses of synthetic DNA oligonucleotides: 296 examples from A-DNA and 280 from B-DNA. The most striking aspect of this plot is the radically different behaviour of A- and B-DNA. The prototypical sugar conformation for A-DNA obtained from fibre diffraction modelling, C3′-*endo*, is, in fact, adhered to quite closely in A-DNA crystal structures.

However, B-DNA shows a quite different behaviour. Although earlier fibre diffraction led one to expect C2′-*endo* sugars, the actual experimental distribution is quite broad, extending up the right-hand side of the pseudorotation circle of Fig. 23.4.2.5, through C1′-*exo*, O1′-*endo* and C4′-*exo*, in some cases all the way to C3′-*endo* itself. Indeed, the mean value of δ observed in B-DNA oligomer crystal structures is 128° rather than 144° (Table 23.4.2.1), making C1′-*exo* a better description of sugar conformation in B-DNA than C2′-*endo*. Old habits die hard, however, and the B-DNA sugar conformation is still colloquially termed C2′-*endo*, a designation of historical significance but of little practical value. The apparent greater malleability of the B helix compared to A may indeed be one feature that makes B-DNA particularly suitable for expressing its base sequence to drugs and control proteins *via* local helix structure changes.

23.4.2.3. Base pairing

The key to the biological role of DNA is that one of the two purines can pair with only one of the pyrimidines: A with

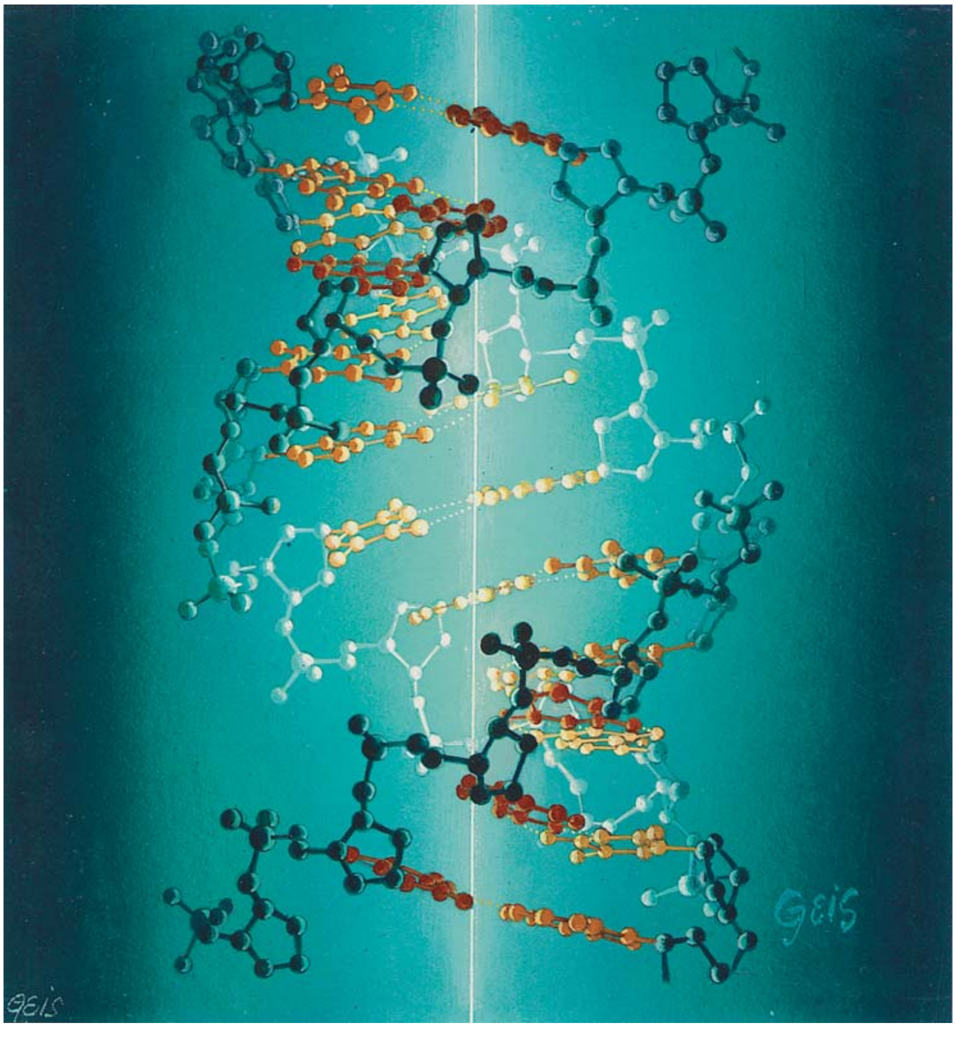

Figure 23.4.1.1
‘Hot wire’ painting of A-DNA by Irving Geis. Geis produced two dramatic paintings of horse-heart cytochrome *c*, in which the sole light source was the central iron atom within the haem, producing a glowing ‘molecular lantern’ effect. One painting showed this central luminous haem surrounded by hydrophobic side chains; the other featured the polar side chains extending out from the surface. These are to be seen today on the front and back covers of Voet & Voet’s *Biochemistry* (Voet & Voet, 1990, 1995). In the present A-DNA painting, Geis chose the imaginary central axis of the helix as a monofilament light source, thereby reversing the conventional illumination: atoms lining the deep major groove glow brightly, whereas the outer surface of the helix is in dark silhouette. Geis struggled with the B helix as an artistic subject, but was never satisfied with the results. Hence, this glowing A-DNA helix represents his nucleic acid artistic legacy. Reprinted courtesy of the estate of Irving Geis. Rights owned by Howard Hughes Medical Institute.

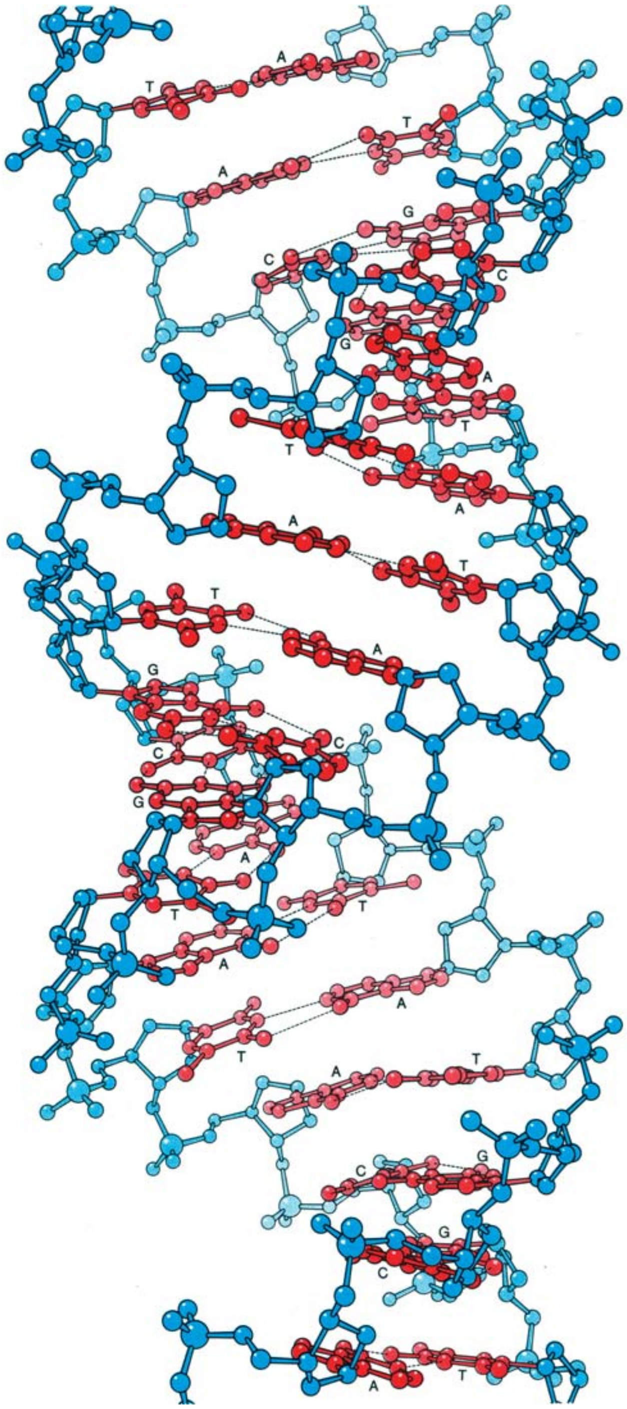

Figure 23.4.1.2

Infinite A-DNA helix, generated from the X-ray crystal structure of the hexamer G-G-T-A-T-A-C-C (references A2 and A7 in Table A23.4.1.1) by deleting the outer base pair from each end and stacking images of the resulting truncated hexamer so their outer phosphate groups overlapped. This generates an endless helix that exhibits the local structural features of the X-ray crystal structure. Note the degree to which the A helix resembles an antiparallel double-stranded ribbon wound around an invisible helical core (the 'hot wire' axis of Fig. 23.4.1.1). (From Dickerson, 1983.) Reprinted courtesy of the estate of Irving Geis. Rights owned by Howard Hughes Medical Institute.

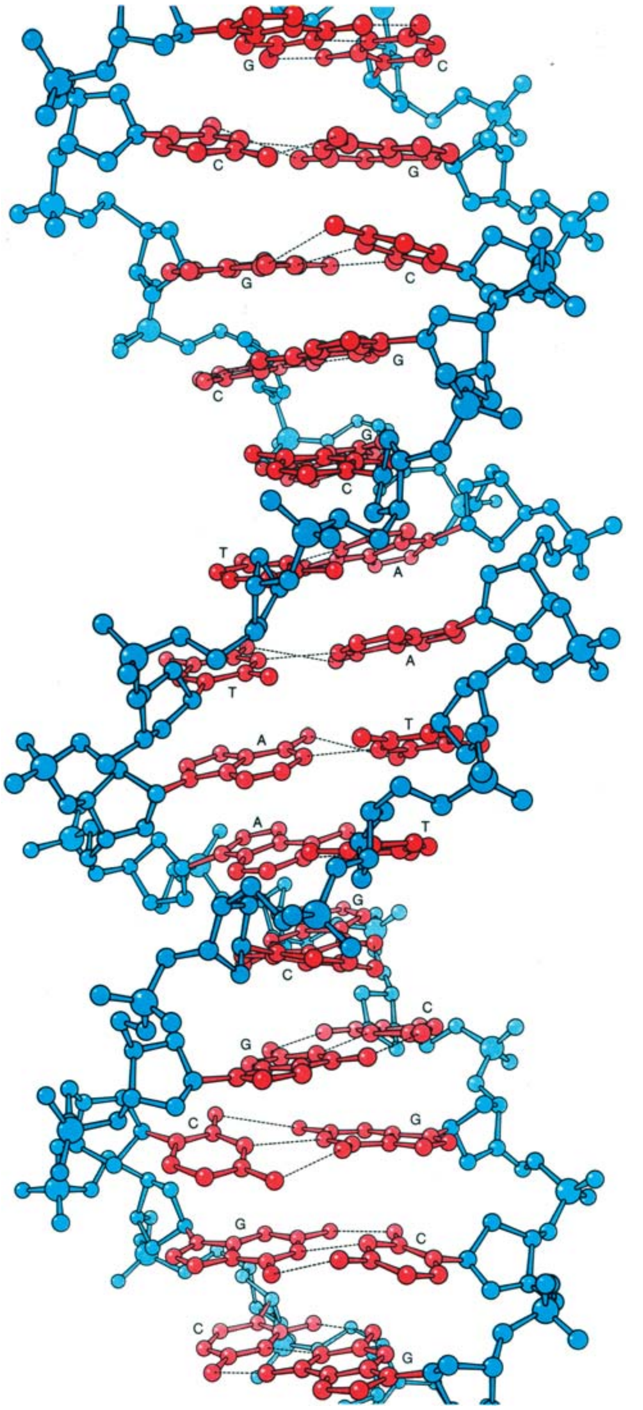

Figure 23.4.1.3

Infinite B-DNA helix, generated in a similar manner to Fig. 23.4.1.2 from the central ten base pairs of the dodecamer C-G-C-G-A-A-T-T-C-G-C-G (B1–B5). Note that the minor groove is narrow in the AT region facing the viewer at the centre, but appreciably wider in the GC regions on the back side of the helix at top and bottom. Propeller twisting, or deviations of bases from coplanarity within one pair, is one sequence-dependent aspect of DNA that was not suspected from the averaged structures obtained from fibres. (From Dickerson, 1983.) Reprinted courtesy of the estate of Irving Geis. Rights owned by Howard Hughes Medical Institute.

T, and G with C. Hence, genetic information present in one strand is passed on to the complementary strand. The standard two-base pairs are shown in Fig. 23.4.2.7 along with the conventional numbering of the atoms. Backbone sugar and phosphate atoms are primed while base atoms are unprimed, as, for example, C1′ and N9 at opposite ends of a purine glycosydic bond. The G·C base pair is held together by three hydrogen bonds, whereas an A·T pair has only two. This means that A·T pairs show less resistance to propeller twisting (counter-rotation of the two bases about their common long axis), and this will have an effect on minor groove width, as seen later. The patterns of hydrogen-bond acceptors (*A*) and donors (*D*) on the major and minor groove edges of base pairs are important elements in recognition of base sequence by drugs and control proteins.

Other related but nonstandard base pairs are compared in Fig. 23.4.2.8. Inosine (I) is useful in studying properties of DNA in

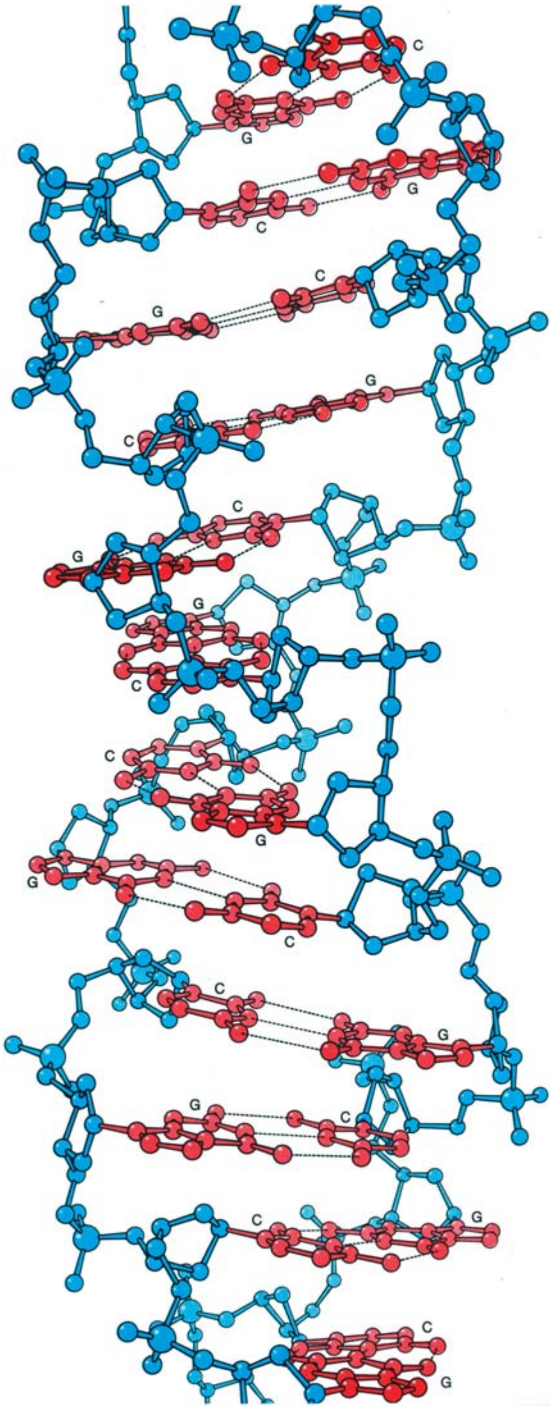

Figure 23.4.1.4
Infinite Z-DNA helix, generated as before from the central four base pairs of the hexamer C-G-C-G-C-G (Z1). G and C bases alternate along each chain. The sugar–phosphate backbone adopts a pronounced zigzag pathway, rising vertically past each guanine, but travelling horizontally across the helix at cytosines. Hence, the formal helix repeat is two base pairs, G followed by C, rather than a single base pair, as in the A and B helices. Note that the structures of Z-DNA and A-DNA are in many ways the inverse of one another. The Z helix is left-handed, tall and slim, with a deep minor groove, a flattened major groove and small propeller twist. The A helix is right handed, short and broad, with a deep major groove, a shallow minor groove and large propeller twist. (From Dickerson, 1983.) Reprinted courtesy of the estate of Irving Geis. Rights owned by Howard Hughes Medical Institute.

that, when paired with cytosine (C), it creates a G·C-family base pair having overall similarity to A·T. Similarly, diaminopurine (DAP) [also known as 2-aminoadenine (2aA)], when paired with thymine (T), creates a G·C-like pair from A·T-family bases.

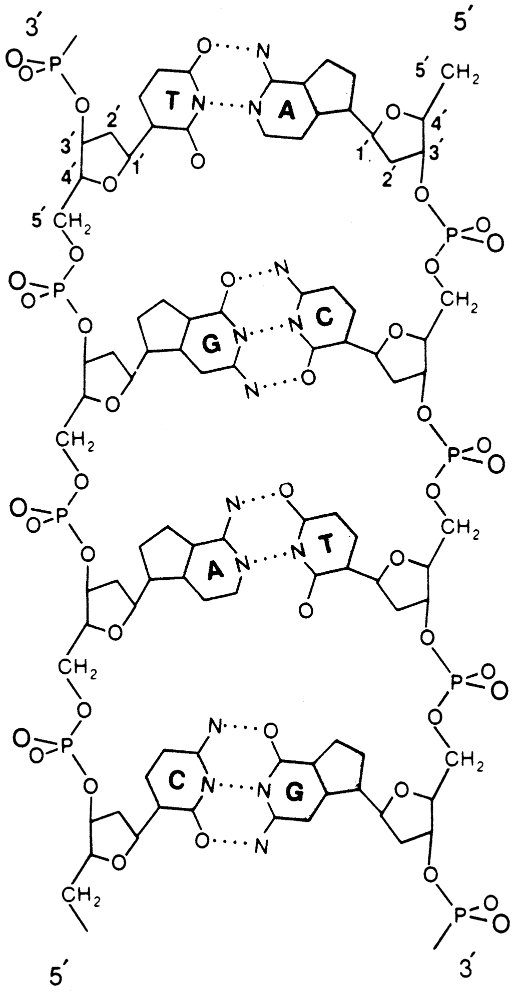

Figure 23.4.2.1
Unrolled schematic of A- or B-DNA, viewed into the minor groove. Paired bases are attached to backbone chains that run in opposite directions: downward on the right and upward on the left. Z-DNA differs from A- and B-DNA in that the two backbone chains run in opposite directions from those shown here. Hence, Z-DNA cannot be obtained from A- or B-DNA by simple twisting around the helix axis.

Hence, in a given experimental situation, one can unscramble the relative significance of number of hydrogen bonds *versus* identity and location of exocyclic groups.

The conventional Watson–Crick base pairing of Fig. 23.4.2.7 uses the hexamer 'end' of the purine base. A different type of base pairing was proposed many years ago by Hoogsteen (1963), in which the upper edge of the purine was used: N7 and N6/O6. Hoogsteen base pairing is shown between the left-hand two bases in each part of Fig. 23.4.2.9. Note that in Hoogsteen base pairing of A and T, each ring provides both a hydrogen-bond donor and an acceptor. Guanine cannot do this, since both its N7 and O6 positions are acceptors. As a consequence, in a G·C pair, C must supply both of the hydrogen-bond donors. It can only form a Hoogsteen base pair with G when the cytosine ring is protonated. This would lead one to expect triplex formation only at low pH. However, the stability of a triplex can, to a certain extent, alter the pK_a of the N—H proton itself. (Recall the shift in pK_a of buried Asp and His groups in the active sites of enzymes.) Hence, with a single-chain DNA, G-A-G-A-G-A-A-C-C-C-C-T-T-C-T-C-T-C-T-T-T-C-T-C-T-C-T-T, that folds back upon itself twice to build a triplex, NMR experiments indicate a significant amount of triplex remaining even at pH 8.0 (Sklenár & Feigon, 1990; Feigon, 1996).

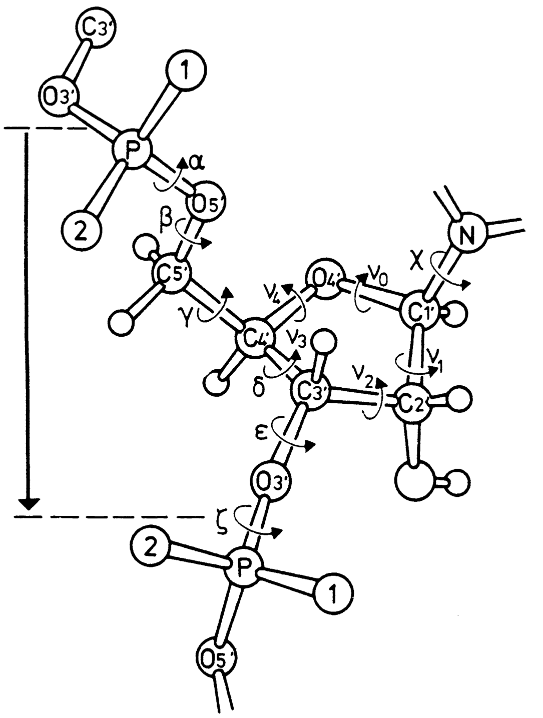

Figure 23.4.2.2
Sugar–phosphate backbone of RNA and DNA polynucleotides. One nucleotide begins at a phosphorus atom and extends just short of the phosphorus atom of the following nucleotide, with the conventional positive direction being $\mathrm{P}\rightarrow\mathrm{O5'}-\mathrm{C5'}-\mathrm{C4'}-\mathrm{C3'}-\mathrm{O3'}\rightarrow\mathrm{P}$, as indicated by the arrows. Main-chain torsion angles are designated α through ζ, and torsion angles about the five bonds of the ribose or deoxyribose ring are ν_0 through ν_4, as shown. If one imagines atoms $\mathrm{O3'}-\mathrm{P}-\mathrm{O5'}$ as a hump-backed bridge, as one crosses the bridge in a positive chain direction, oxygen atom O1 is to the left and O2 is to the right. These oxygens, accordingly, are sometimes designated O_L and O_R. The $-\mathrm{OH}$ group attached to the C2′ atom of the ribose ring in RNA shown here is replaced by $-\mathrm{H}$ in the deoxyribose ring of DNA. Atom N to the right is part of the base attached to the sugar ring: N1 in pyrimidines and N9 in purines. Torsion angle χ is defined by $\mathrm{O4'}-\mathrm{C1'}-\mathrm{N1}-\mathrm{C2}$ in pyrimidines and $\mathrm{O4'}-\mathrm{C1'}-\mathrm{N9}-\mathrm{C4}$ in purines.

23.4.2.4. Helix parameters

An important advantage of single-crystal oligonucleotide structures over fibre-based models is that one can actually observe local sequence-based departures from ideal helix geometry. B-DNA fibre models indicated a mean twist of *ca* 36° per step, or ten base pairs per turn, whereas A-DNA fibre patterns indicated less winding: *ca* 33° per step or 11 base pairs per turn. Twist, rise per base pair along the helix axis, horizontal displacement of base pairs off that axis, and inclination of base pairs away from perpendicularity to the axis are all intuitively obvious parameters. But when single-crystal structures began appearing in great numbers in the mid-1980s, it became imperative that uniform names and definitions be used for these and for less obvious, but increasingly significant, local helix parameters.

An EMBO workshop on DNA curvature and bending, held at Churchill College, Cambridge, in September 1988, led to an agreement on definitions and conventions that was published simultaneously in four journals (Dickerson *et al.*, 1989). Fig. 23.4.2.10 shows the reference frames for two successive base pairs, and Figs. 23.4.2.11 and 23.4.2.12 illustrate local helix parameters involving rotation and translation, respectively. Subsequent experience has shown the most useful parameters to be inclination, propeller, twist and roll among the rotations, and x displacement, rise and slide among the translations. As mentioned at the beginning of this chapter, inclination and x displacement are the two properties that best differentiate A- from B-DNA. The four most widely used computer programs for calculation of local helix parameters are *NEWHELIX* by Dickerson (B7, B46), *CURVES* by Lavery & Sklenar (1988, 1989), *BABCOCK* by Babcock & Olson (Babcock *et al.*, 1993, 1994; Babcock & Olson, 1994) and *FREEHELIX* (Dickerson, 1998*c*). *NEWHELIX* was the earliest of these, but it performs all calculations relative to a best overall helix axis. This is satisfactory for single-crystal DNA structures, but makes the program unusable for the 180° bending observed in some protein–DNA complexes. *CURVES* is especially convenient for mapping the axis of a bent or curved helix. *FREEHELIX*, which evolved from *NEWHELIX*, calculates all parameters relative to local base-pair geometry, without assuming an overall axis, and permits display

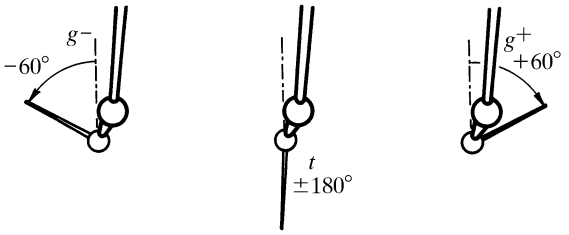

Figure 23.4.2.3
Definition of torsion angles. A positive angle results from clockwise rotation of the farther bond, holding the nearer bond fixed. Torsion angle +60° is designated as *gauche*$^+$ or g^+, angle 180° is *trans* or *t* and angle −60° is *gauche*$^-$ or g^-.

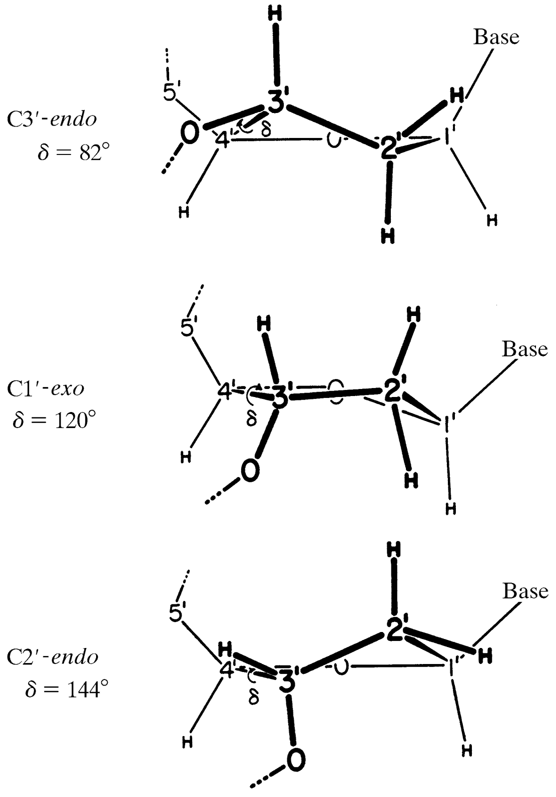

Figure 23.4.2.4
The three most common furanose ring geometries. The planar form of the five-membered ribose or deoxyribose ring is unstable because of steric hindrance from side groups; one of the five atoms prefers to pucker out-of-plane on one side of the ring or the other. Puckering toward the same side of the ring as the C5′ atom is termed *endo*, and puckering toward the opposite 'outside' surface is termed *exo*. The main-chain torsion angle δ is related to sugar ring conformation because of the motion undergone by the $\mathrm{C3'}-\mathrm{O3'}$ bond during changes in puckering.

Table 23.4.2.1
Average torsion-angle properties of A-, B- and Z-DNA (°)

Values listed are mean torsion angles, with standard deviations in parentheses. Conformations are only approximate; — indicates a non-*gauche/trans* conformation. B_{II} and Z_{II} are less common variants. For δ, the sugar ring geometry is quoted in place of *gauche/trans*. χ for B-DNA combines pyrimidines and purines. Values were obtained from a sample of 30 A-DNAs, 34 B-DNAs, 22 Z-DNAs and ten nonstandard DNAs in the Nucleic Acid Database. From Schneider *et al.* (1997).

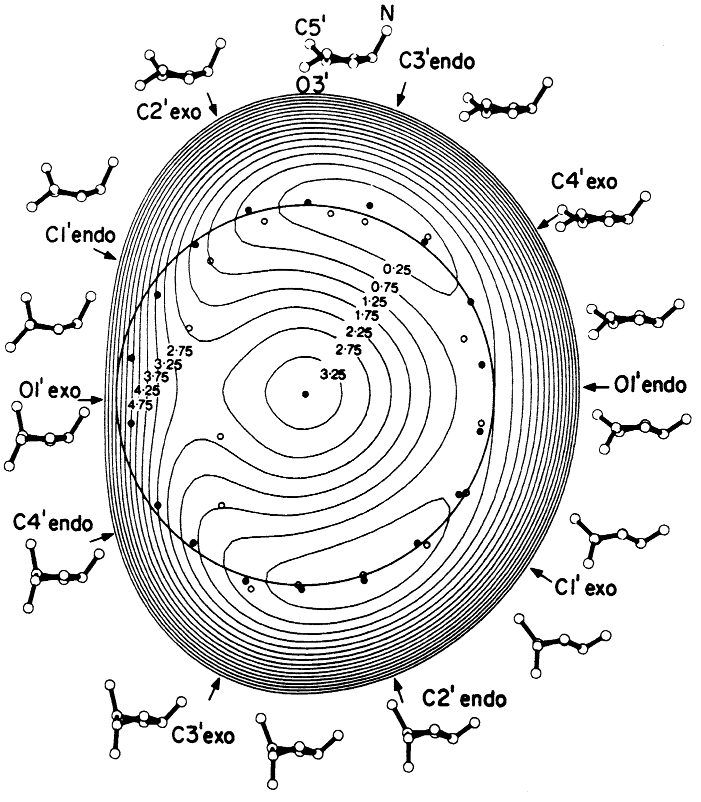

Figure 23.4.2.5
Potential plot of all furanose ring conformations. Energies are in kcal mol^{-1}. The distance from the central point gives the maximum displacement of the out-of-plane atom from the plane of the other four. The circle is a constant-displacement trajectory chosen to pass through the potential minima on the right three-quarters of the plot. C2′-*endo* and C3′-*endo* are especially favoured, whereas O1′-*exo* on the left is highly disfavoured. The path from C2′-*endo* through C1′-*exo*, O1′-*endo* and C4′-*exo* to C3′-*endo* is a low-energy path, and many examples all along this path are known in B-DNA helices. C2′-*exo*	342	96

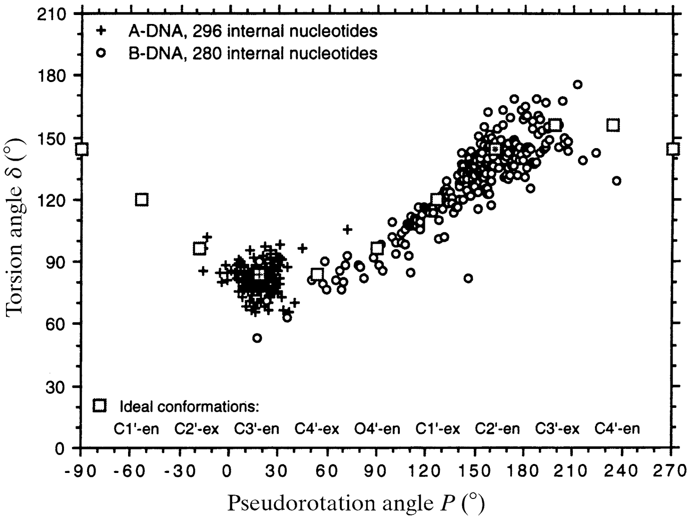

Figure 23.4.2.6
Plot of observed sugar conformations in 296 nucleotides of A-DNA (crosses) and 280 of B-DNA (open circles). Open squares mark ideal relationships between torsion angle δ (vertical axis) and pseudorotation angle P (horizontal axis) from the expression $\delta = 40° \cos(P + 144°) + 120°$. Deviations from this ideal curve for real helices arise, because the amplitude of pseudorotation (or displacement of one atom from the mean plane of the others) varies from one ring to another. Note the tight clustering of A-DNA points around C3′-*endo* and the broader distribution of B-DNA conformations.

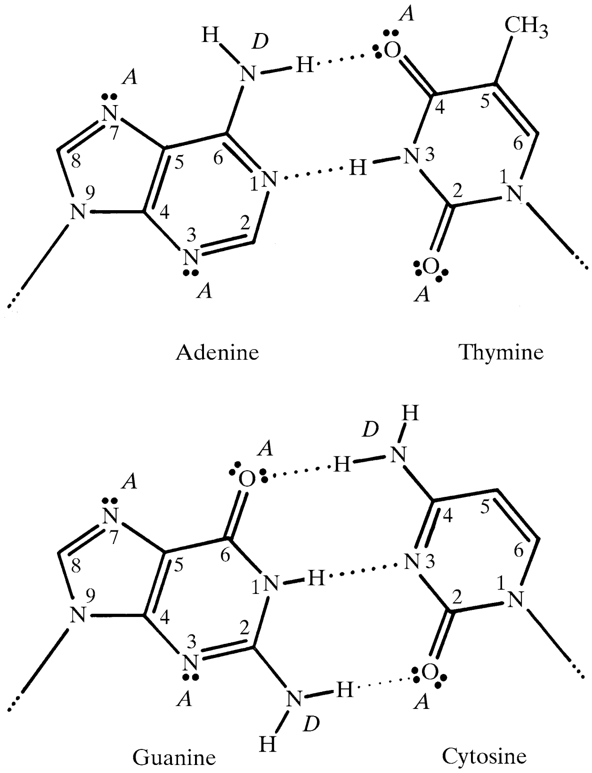

Figure 23.4.2.7
A·T and G·C base pairs with minor groove edge below and major groove edge above. *A* is a hydrogen-bond acceptor, *D* is as hydrogen-bond donor.

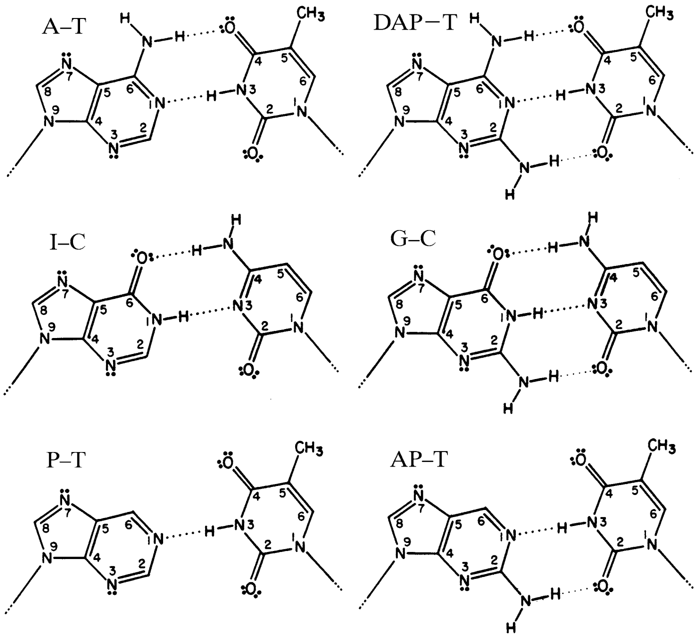

Figure 23.4.2.8
Alternative purines and pyrimidines, and possible base pairings. Purines: P = purine; AP = 2-aminopurine; A = adenine or 6-aminopurine; DAP = 2,6-diaminopurine (also known as 2aA = 2-aminoadenine); G = guanine; I = inosine. Pyrimidines: T = thymine (uracil if methyl group is absent); C = cytosine. DAP–T is a nonstandard AT-family analogue of G–C, and I–C is a nonstandard GC-family analogue of A–T.

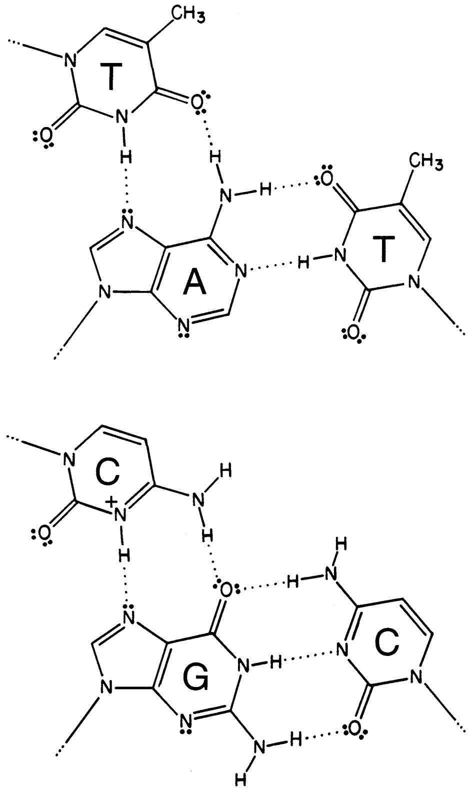

Figure 23.4.2.9
Watson–Crick pairing of a purine (A or G) with a pyrimidine to its right (T or C), and Hoogsteen pairing of the same purine with a pyrimidine above it. This combination of Watson–Crick and Hoogsteen pairing is found in triple helices or triplexes. Note that Hoogsteen pairing of G and C can only occur at a pH at which C is protonated, because the extra proton is essential for the second hydrogen bond.

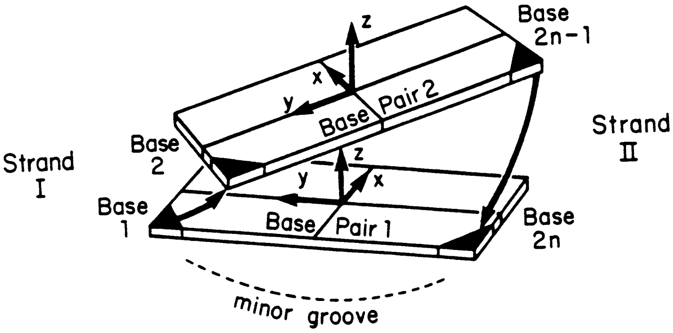

Figure 23.4.2.10
Definitions of local reference axes (x, y, z) at the first two base pairs of an n-base-pair double helix. Base 1 is paired with base $2n$, base 2 with base $2n - 1$ *etc.* Shaded corners represent attachment points to sugar rings. Curved arrows denote 5′-to-3′ 'positive' directions of each backbone chain. Note that when looking into the minor groove, as here, the two strands illustrate a clockwise rotation, upwards on the left and downwards on the right. This is true for A- and B-DNA, but for Z-DNA, the sense of the two backbone strands is reversed.

of normal vector plots that are especially useful in analysing bending in DNA–protein complexes (Dickerson & Chiu, 1997).

23.4.2.5. Syn/anti glycosyl bond geometry

The glycosyl bond angle, χ, about the bond connecting a sugar ring to a base is a special case of torsion angle, and is defined by O4′—C1′—N1—C2 for pyrimidines and O4′—C1′—N9—C4 for purines. In A- and B-DNA, the normal range of χ is 160 to 300°. This is known as the *anti* conformation (right-hand side of Fig. 23.4.2.13) and swings the sugar ring out away from the minor groove edge of the base pair. In Z-DNA, pyrimidines also exhibit the *anti* glycosyl bond conformation, but purines adopt the *syn* geometry shown on the left-hand side of Fig. 23.4.2.13. Now the sugar ring is rotated so that it intrudes into the minor groove, and χ lies in the range 50 to 90°.

23.4.3. Comparison of A, B and Z helices

Figs. 23.4.3.1–23.4.3.3 show the original stereo pairs that were redrawn by Irving Geis in preparing Figs. 23.4.1.2–23.4.1.4. These stereo pairs were constructed from X-ray structures of A-, B- and Z-DNA oligomers by deleting the outermost base pair from each end, eliminating the backbone as far as the first phosphate group, and then stacking these trimmed-down helices on top of one another, with phosphate groups overlapping, to create an infinite

Figure 23.4.2.13
Syn versus anti orientation about the glycosyl bond connecting sugar and base. Right: *anti* conformation, with χ *ca* 210°. Left: *syn* conformation, with χ around 60°. Both A- and B-DNA only employ the *anti* geometry; Z-DNA uses *anti* for pyrimidines and *syn* for purines, as shown here. Note that the 5′-to-3′ direction in both rings is down into the paper. Hence, antiparallel backbone chains can be achieved only by a zigzag chain geometry with local chain reversals, as shown later in Fig. 23.4.3.4. Black dots labelled A, B and Z indicate the position of the helix axis relative to the base pairs in A-, B- and Z-DNA.

helix. They are improvements over the idealized infinite helices generated from fibre diffraction in that they display local variation in helix parameters that only single-crystal analyses can reveal. In the present context, they are good subjects for discussion of the differences between the three helix types.

23.4.3.1. *x* displacement and groove depth

A-DNA (Wahl & Sundaralingam, 1996, 1998), B-DNA (Berman, 1996; Dickerson, 1998*b*) and Z-DNA (Ho & Mooers, 1996; Basham *et al.*, 1998) have each been the subject of recent reviews, to which the reader is referred for details that cannot be covered here. The distinctive properties of the three helices are listed in Table 23.4.3.1. The most obvious distinction is handedness: A and B are right-handed helices, whereas Z is left-handed. Moreover, the position of each base pair relative to the helix axis is quite different. As noted in Fig. 23.4.2.13, the helix axis passes through base pairs in B-DNA, lies on the minor groove side of base pairs in Z-DNA, and on the major groove side in A-DNA. In terms of the helix parameters of Fig. 23.4.2.12, A-DNA has a typical *x* displacement of d_x = +3 to +5 Å, B-DNA has d_x = −1 to 0 Å, and Z-DNA has d_x = −3 to −4 Å. There is virtually no overlap between these three ranges; *x* displacement, d_x, in fact, is a better criterion for differentiating the three classes of helix than is sugar ring conformation.

A direct consequence of these *x* displacement values is great differences in depths of major and minor grooves. Both grooves are of equivalent depth in B-DNA because base pairs sit on the helix axis. In A-DNA, a base pair is pushed off-axis so that its minor edge approaches the helix surface, making the minor groove very shallow and the major groove cavernously deep. In Z-DNA, it is the major edge of each base pair that is pushed toward the surface, so that the minor groove is deep and the major groove is so shallow as hardly to be characterized as a groove at all. It is sometimes stated that 'Z-DNA has no major groove', but space-filling stereos, such as Fig. 1 of reference Z6 or Fig. 3 of Z23 reveal the shallowest of major grooves running around the helix cylinder, flanked by very slightly higher phosphate backbones.

23.4.3.2. Glycosyl bond geometry

In both A- and B-DNA, all glycosydic bonds are *anti*, with sugar rings swung to either side away from the minor groove, as in Fig. 23.4.3.4(*a*). As mentioned earlier, when viewed into the minor groove, the backbone chains describe a clockwise rotation, with the chain on the right running downward, and that on the left upward, as in Fig. 23.4.2.1. In Z-DNA, both chains run in the *opposite* direction, leading to a counterclockwise rotation sense viewed into the minor groove. But Z-DNA has yet another striking (and defining) feature. Purines and pyrimidines alternate along each chain. G and C are most strongly favoured by far, but A and T can substitute intermittently at a price in stability. Breaking the strict alternation of purines and pyrimidines is even more unfavourable and is rarely encountered in crystal structures (Table A23.4.1.3). At each purine base, the glycosyl bond is rotated into the minor groove to the *syn* position, as in Fig. 23.4.3.4(*c*). This causes the local backbone

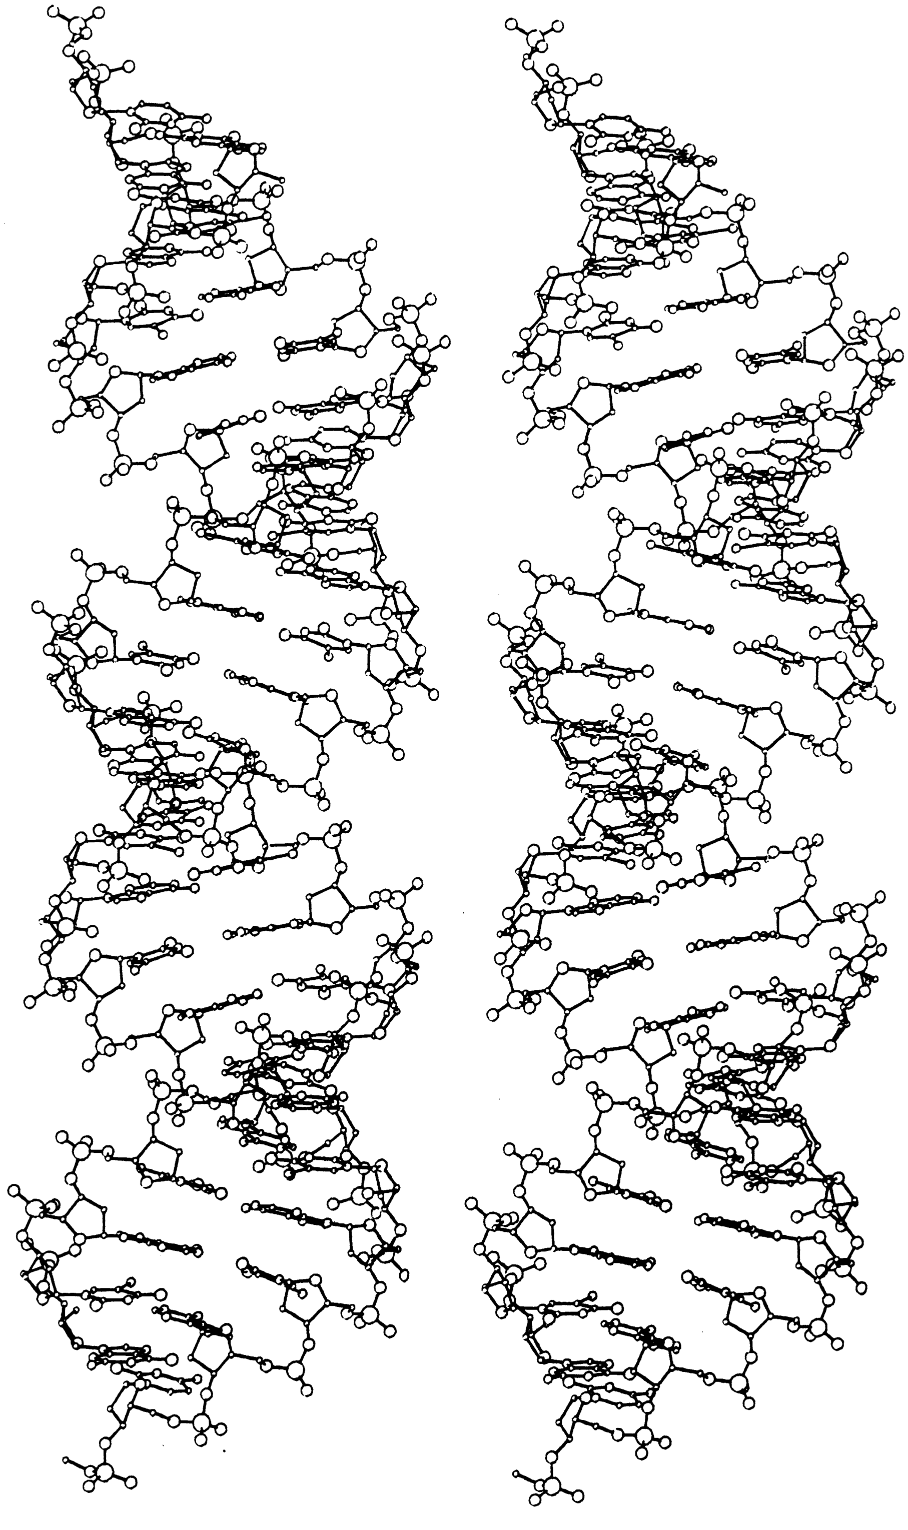

Figure 23.4.3.1
The A-DNA stereo pair drawing from which Fig. 23.4.1.2 was derived, with repeating sequence -(G-T-A-T-A-C)$_n$-. The impression of the A helix as a ribbon wrapped around an imaginary core is even more strongly developed in this stereo. (From Dickerson, 1983.)

directions, defined by sugar ring atoms C4′ and C3′, to be parallel in the two strands. Z-DNA avoids becoming a parallel-chain helix by performing a local chain reversal at each pyrimidine. In Fig. 23.4.3.4(*c*), although the local C4′–C3′ chain direction at the cytosine sugar is downward, the double loop in backbone chain gives it a net upward orientation. In stereo Fig. 23.4.3.3, the ascending backbone chain rises smoothly past each guanine, with a chain path parallel to the helix axis. However, the chain bends abruptly at right angles when passing a cytosine, in a direction tangential to the helix cylinder. Guanine sugar rings point their O4′ oxygen atoms in the backward chain direction (as is also true for all bases in A- and B-DNA), but cytosine sugars point their oxygens in the forward direction. This 'up at G, across at C' pathway and inversion of sugar rings is what produces the zigzag backbone pathway that leads to the name Z-DNA. The O4′ atom of each cytosine sugar is stacked on top of the guanine ring of the subsequent nucleotide, and this stacking of a polar O (or N) on top of a polarizable aromatic ring contributes to the stability of the Z helix, as it does to many other base–base interactions to be discussed later (Bugg *et al.*, 1971; Thomas *et al.*, 1982; B32).

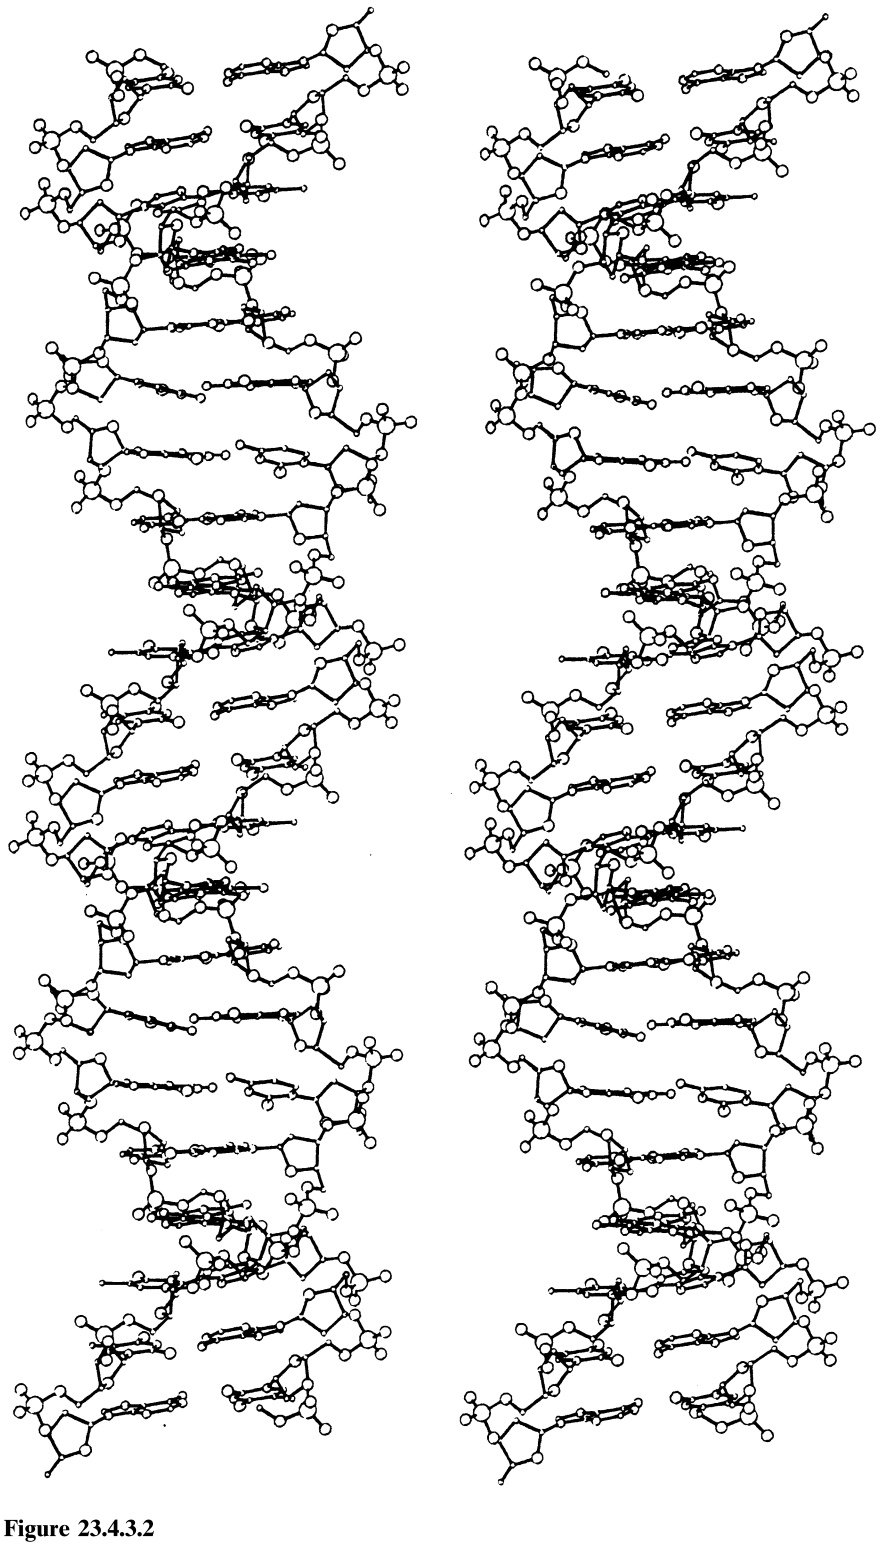

Figure 23.4.3.2
The B-DNA stereo pair drawing from which Fig. 23.4.1.3 was derived, with repeating sequence -(G-C-G-A-A-T-T-C-G-C)$_n$-. The variation of minor groove widths on the front and back sides of the helix is striking. (From Dickerson, 1983.)

23.4.3.3. *Sugar ring conformations*

Sugar ring conformations in A- and B-DNA have a logical structural basis. The B-DNA backbone is more extended than the A-DNA backbone, with P–P distances of *ca* 6.6 Å along one chain, compared with *ca* 5.5 Å in A-DNA. In turn, C2′-*endo* is a more extended ring conformation than C3′-endo, demonstrable in Fig. 23.4.2.4 by a greater distance between C5′ and O3′ atoms. Hence, it is logical that the more extended ring conformation should be associated with the more extended backbone chain. In Z-DNA, the extended C2′-*endo* form is adopted at cytosine, where a zigzag double chain reversal must be accommodated, while the more compact C3′-*endo* occurs at the straight backbone segment running past a guanine.

The cramped *syn* glycosyl conformation is strongly disfavoured, although not absolutely forbidden, at pyrimidines, most probably because of steric clash between the pyrimidine O2 and the *syn* ring (Haschmeyer & Rich, 1967; Davies, 1978; Ho & Mooers, 1996; Basham *et al.*, 1998). Hence, the Z-DNA helix is effectively limited to alternating pyrimidine/purine sequences, with a price that must be paid for intermittent substitution of A and T for G and C, and an even higher price paid for breaking the pyrimidine/purine alternation. This is reflected in the X-ray crystal structures listed in Table A23.4.1.3. Only one non-alternating sequence has been completely solved and published: *C-G-G-G-*C-G (Z40), where adoption of the Z form has been forced by 5-methylation of cytosines (*C). A second non-alternating sequence that includes AT base pairs, *C-G-A-T-*C-G (Z13), was solved in 1985, but its coordinates have never been made public. It, too, required methylation of cytosines to induce the Z form. A third sequence, C-C-G-C-G-G (Z42), opens its terminal base pairs to make intermolecular base pairs with crystal neighbours. The 52 remaining Z-DNA structures in Table A23.4.1.3 all have strict alternation of pyrimidines and purines.

23.4.3.4. *Helical twist and rise, and propeller twist*

The helical repeat unit in Z-DNA is therefore two successive base pairs, rather than the single base pair of A- and B-DNA. Ho & Mooers (1996) propose that the C-G or $^{5'}$pyrimidine-P-purine$^{3'}$ step be considered the fundamental unit of the Z-helical structure, because of the tight overlap between the two base pairs. As can be seen in Fig. 23.4.3.3, in a C-G step the pyrimidine rings from the two base pairs actually stack over one another, whereas the purine rings are packed against neighbouring sugar O4′ atoms. Helix-axis rotation at this step is only −8°, whereas the preceding and following G-C steps have a mammoth −52° twist. Hence, although Z-DNA has 12 base pairs per turn, it technically is not a dodecamer helix, but a hexamer with a two-base-pair repeating unit and a total rotation of −60° per unit.

This virtual restriction to purine/pyrimidine alternation means that Z-DNA cannot be involved in the coding of genetic information. A and B helices have no such restriction; their structures can accommodate a random sequence of bases. Average twist angles are as shown in Table 23.4.3.1, although extreme variation in twist is observed at individual steps in single-crystal structure analyses, from as little as 16° to as much as 55°. Base-sequence preferences for local helix parameters are discussed below.

In both B and Z helices, base pairs are very nearly perpendicular to the helix axis, whereas in the winding double ribbon of A-DNA, the long axis of each base pair is inclined by 10 to 20° away from perpendicularity to the axis. Hence, the rise per base pair for all B-helical steps and for G-C steps of Z-DNA is equal to the thickness of a base pair, 3.4 Å. The rise at a C-G step of Z-DNA is larger because it involves stacking of a sugar oxygen on each purine ring, not ring stacked on ring. For A-DNA, the rise along the helix axis can actually be less than the thickness of a base pair, because adjacent base pairs are stacked at an incline. The perpendicular distance from one base pair to the next in A-DNA is still 3.4 Å. Both A- and B-DNA exhibit considerable base pair propeller twist, especially at A·T pairs with only two hydrogen bonds rather than three. In contrast, Z-DNA, with predominately G·C pairs, shows only a small propeller twist.

The stacking of base pairs has immediate consequences for crystal growth. For Z-DNA, four base pairs are one-third of a helical turn, and six base pairs are a half turn. Hexamers are the most common crystal form in Table A23.4.1.3 by a large majority. In contrast, octamers and decamers are not simple fractions of a turn, and they stack in a disordered manner. One would predict that dodecamers of Z-DNA might crystallize well if the oligomers were not so long as to fall prey to cylindrical disorder.

By the same principles, B-DNA decamers stack easily and well to build pseudo-infinite helices through the crystal, with ordered cylindrical rods packed in six different space groups. The other common crystallization mode for B-DNA, the dodecamer, has a two-base-pair overlap of ends that both stablizes the crystals and yields a functional ten-base-pair repeat. (See Fig. 2 of Dickerson *et al.*, 1987.) Because the dodecamers are held by their outer two base pairs, the central eight pairs are unobstructed and accessible in the crystal, making dodecamers particularly good subjects for the study of minor-groove binding drugs.

A-RNA duplexes [Table A23.4.1.1, part (*k*)] also stack end-for-end in a manner simulating an infinite A helix, even though the end base pairs are inclined and are not perpendicular to the helix axis. This behaviour has been seen for octamers with roughly two-thirds of a helical turn, for nonamers, and for dodecamers with roughly a full turn.

In contrast, crystals of A-DNA behave quite differently. Regardless of chain length, A-DNA helices crystallize with the outer base pair of one helix packed against one wall of the broad, open and relatively hydrophobic minor groove of another helix. This packing mode is sufficiently adaptable to accommodate duplexes of lengths four, six, eight, nine, ten and 12 base pairs. Hence, A-DNA does not

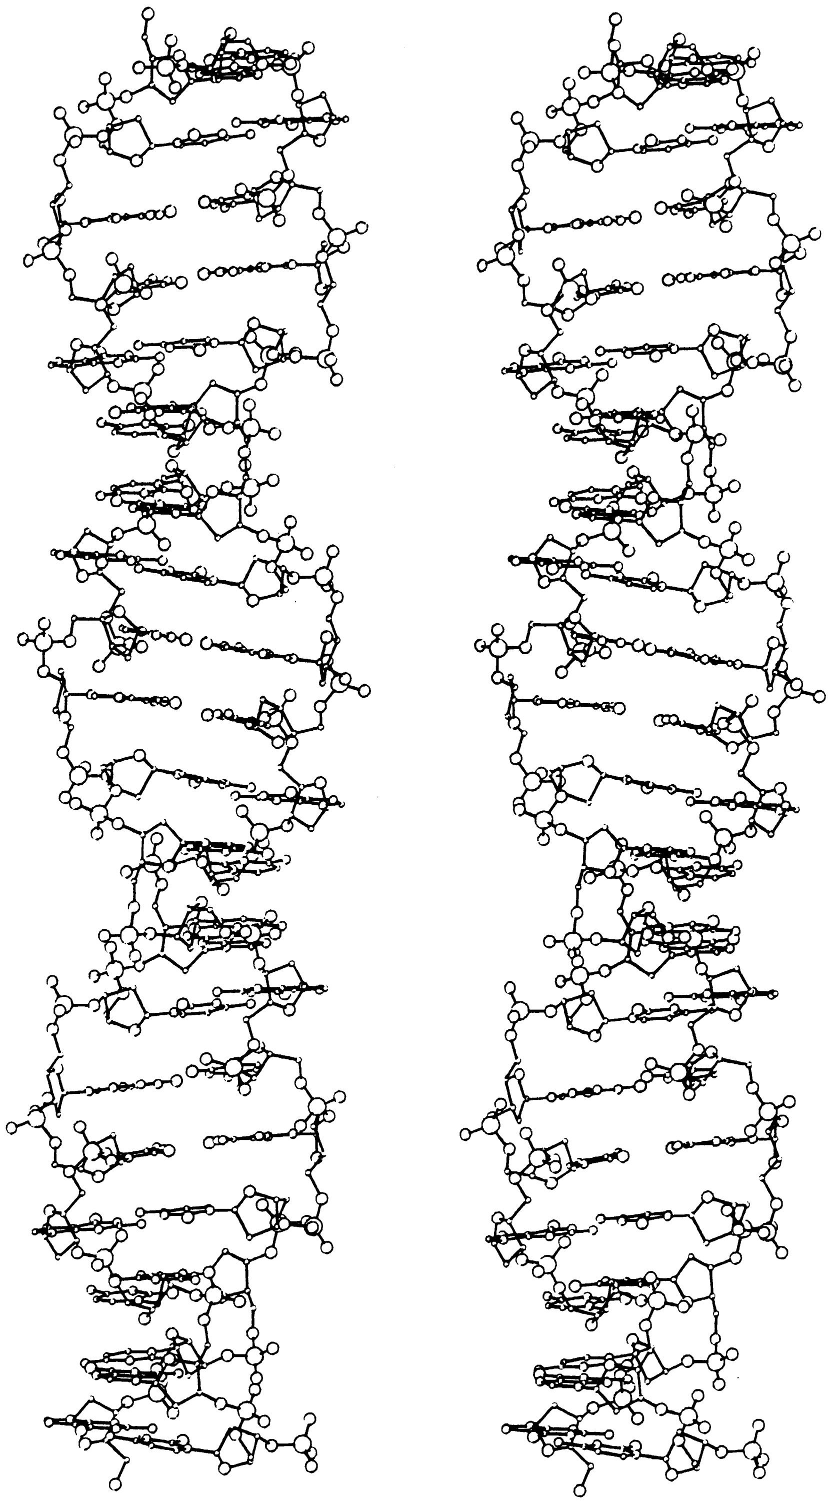

Figure 23.4.3.3
The Z-DNA stereo pair drawing from which Fig. 23.4.1.4 was derived, with repeating sequence -(G-C-G-C)$_n$-. Note the left-handed zigzag path of the sugar–phosphate backbone, which led to its designation as the Z helix. (From Dickerson, 1983.)

Table 23.4.3.1
Comparison of structures of A, B and Z helices

	A	B	Z
Handedness	Right	Right	Left
Helix axis relative to base pairs	Major groove side	Through centre of base pair	Minor groove side
Major groove	Very deep and narrow	Wide, same depth as minor	Very shallow and broad
Minor groove	Shallow and broad	Variable, same depth as major	Very deep and narrow
Glycosydic bonds	*anti*	*anti*	C: *anti* G: *syn*
Minor groove backbone chain sense†	Clockwise	Clockwise	Counterclockwise
Sugar conformation	C3′-*endo* (narrow range)	C1′-*exo*/C2′-*endo* (broad range)	C: C2′-*endo* G: C3′-*endo*
Base pairs per helix repeat	1	1	2
Base sequence limitations	None	None	Alternating (C-G)$_n$ or close variants
Rise per base pair (average)	2.9 Å	3.4 Å	C-G: 4.1 Å G-C: 3.5 Å
Base pair inclination	10–20°	*ca* 0°	*ca* 0°
Mean twist angle	30–33°	34–36°	C-G: −8° G-C: −52°
Helix repeats per turn	11–12	10–10.5	6 (2 base pairs)
Propeller twist	Often substantial, 0–25°	Often substantial, 0–25°	Usually small
Common biological occurrence	RNA	DNA	None?

† Relative 5′-to-3′ directions of the two backbone chains, when viewed into the minor groove.

simulate infinite helices through the crystal lattice, as A-RNA and B- and Z-DNA do.

23.4.3.5. *Allowable RNA helices*

So far this discussion has only been concerned with DNA. Which of the three helix types can be adopted by RNA? Fig. 23.4.3.5 shows that addition of a 2′-OH group to a B-DNA helix [part (*a*)] creates severe steric clash with the phosphate group and sugar ring of the following nucleotide, whereas in an A helix [part (*b*)], the added hydroxyl group extends radially outward from the helix cylinder and causes no steric problems. Hence, the natural helical form for RNA is the A helix, not the B helix. Table A23.4.1.1 shows several single-crystal analyses of A-RNA and RNA/DNA hybrids; Table A23.4.1.2 shows no B-RNA structures. One RNA/DNA hybrid is known as a Z helix: C-G-c-g-C-G (Z24), in which the two central nucleotides are RNA. If one mentally adds an —OH to each C2′ atom in Fig. 23.4.3.3, on the same side of the ring as O3′, it is apparent that the C2′-OH is not inherently incompatible with the Z helix, as it is with the B helix. At guanine sugars, the C2-OH points out and away from the helix, while at cytosine sugars it points away from the base into the spacious minor groove.

23.4.3.6. *Biological applications of A, B and Z helices*

The B helix is the biologically relevant structure for DNA. The A form might logically be adopted at the stage of transient DNA–RNA duplexes during transcription, but elsewhere the B form holds sway. It was once thought that binding of DNA to a protein surface, most particularly nucleosomal winding, might constitute a sufficient dehydration of bound water molecules from the DNA duplex to shift it to the A form. This proved to be false; nucleosomal DNA clearly retains the B conformation. The closest that one comes to biological A-DNA is local deformations upon binding of B-DNA to a few proteins that have been described as ‘A-like distortions’. On the other hand, the A helix has been found repeatedly in RNA duplexes, including tRNA and ribozymes.

The situation is even more restrictive with the Z helix. Although its alternating purine/pyrimidine sequence makes it unusable for genetic *coding*, the suggestion has been made on many occasions that Z-DNA might be an important element in genetic *control* by being involved in negative supercoiling (Herbert & Rich, 1996). It has been shown that a left-handed DNA conformation can be induced by negative superhelical stress, but it is not absolutely clear that this induced, left-handed

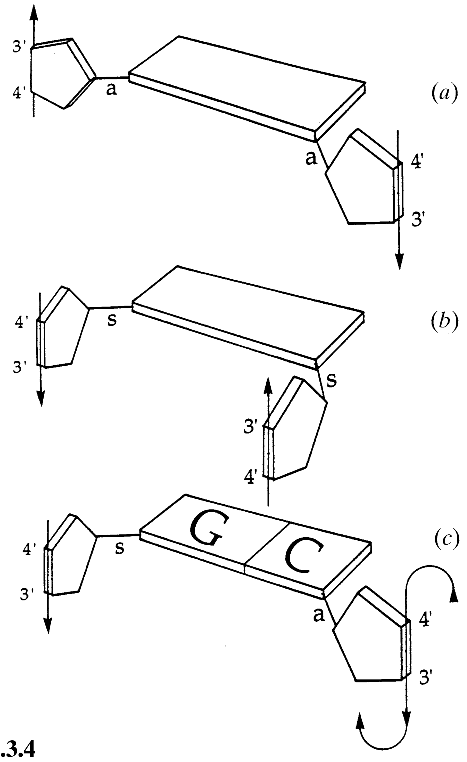

Figure 23.4.3.4
Glycosyl conformation and chain sense. (*a*) Glycosyl conformations *anti*/*anti*, backbone chains antiparallel, with clockwise sense when viewed into the minor groove, as here. This is typical for A- and B-DNA. (*b*) Glycosyl conformation *syn*/*syn*, backbone chains antiparallel, with counterclockwise sense viewed into minor groove. This is not known for any nucleic acid duplex. (*c*) Glycosyl conformation *syn* at G and *anti* at C, with the C4′—C3′ edge of the sugar pointing downward in both strands, which would seem to imply a parallel-stranded helix. However, in Z-DNA, antiparallel strands are achieved by a local reversal of chain direction at each C, as shown here. This produces the zigzag backbone pathway that is characteristic of the Z helix, visible in Fig. 23.4.3.3.

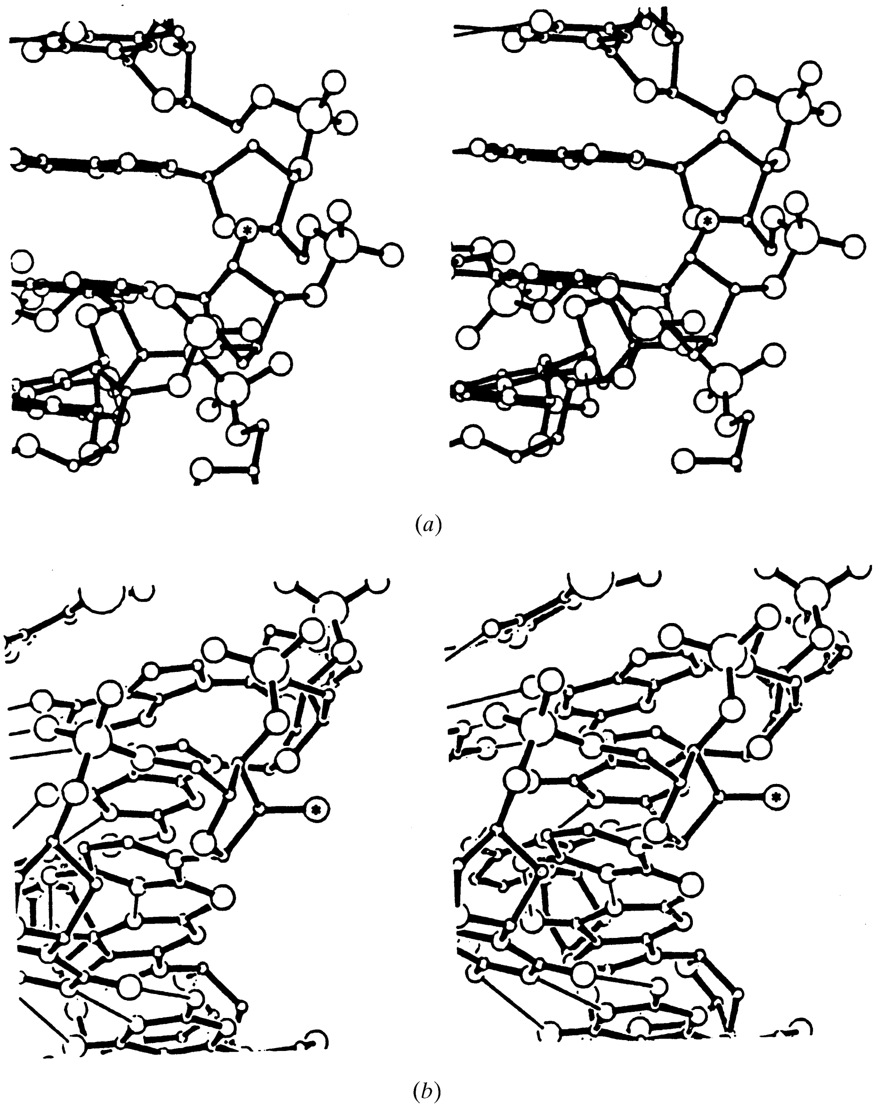

Figure 23.4.3.5
The role of the C2′-OH in RNA helix geometry. (*a*) Addition of a C2′-OH group (*) to the B-DNA helix leads to close contacts and unallowable steric hindrance with the following O5′ and O4′ atoms and, to a lesser degree, the subsequent base itself. (*b*) A C2′-OH group added to the A-DNA helix extends outward radially from the helix cylinder surface and produces no steric clashes. Hence, A-RNA is quite possible, whereas B-RNA is disallowed.

conformation is the same as the Z helix seen in crystal structures of small oligomers. As noted by Herbert & Rich (1996), after nearly twenty years of enquiry, it is still far from certain that Z-DNA itself has any demonstrable biological role.[1]

A major stumbling block is the cumbersome mechanism that must be invoked to explain a B-to-Z interconversion. As mentioned previously, a simple twisting of the helix from right to left is not sufficient, because the backbone chains run in opposite directions in the two forms. Fig. 23.4.3.6 demonstrates the steps that must still be undertaken after both B and Z helices have been unwound so as to remove all of their helical character. Note the opposite sense of the backbone strands in B [part (*a*)] and Z [part (*e*)]. In order to accomplish the interconversion, base pairs of B-DNA must be pulled apart, as in part (*b*), and each base pair swung around to the opposite side of the backbone 'ladder' [part (*c*)]. This would automatically lead to *syn* conformations at both ends of the base pair, as drawn in Fig. 23.4.3.4(*b*). Returning pyrimidines to an *anti* conformation would create the zigzag backbone chain (Fig. 23.4.3.4*c*). Base pairs can then be restacked, as in parts (*d*) and (*e*) in Fig. 23.4.3.6 (which differ only by rotation of the entire helix about the vertical), to yield the backbone geometry of a Z helix. This is the simplest interconversion and one which was recognized and proposed in the very first Z-DNA structure paper (Z1). Other alternatives have been suggested, involving breaking individual base pairs, swinging the bases independently around their backbone chains, and re-forming the pairs. But one kind of special mechanism or another must be invoked if a B-to-Z interconversion is to be achieved.

23.4.3.7. 'Watson–Crick' Z-DNA

Ansevin & Wang (1990) have proposed an alternative left-handed double helix, with many of the properties of Z-DNA, but possessing the same backbone chain orientations as A- and B-DNA. With such a helix, a B-to-Z conversion would require only a twisting of the duplex about its axis – no separation of bases or unpairing, and no pulling apart of the stack. Ansevin & Wang did not challenge the X-ray crystal structure analyses of short Z-DNA oligomers. Instead, they suggested that Z-DNA was globally the most stable form, adopted in short oligomers where chain unravelling and rearrangement is easy, but that their 'Watson–Crick' Z-DNA or Z(WC)-DNA was the structure that was actually produced by *in vitro* or *in vivo* manipulations of long DNA duplexes. They noted that most solution measurements focus on only two characteristics of the DNA: left-hand-

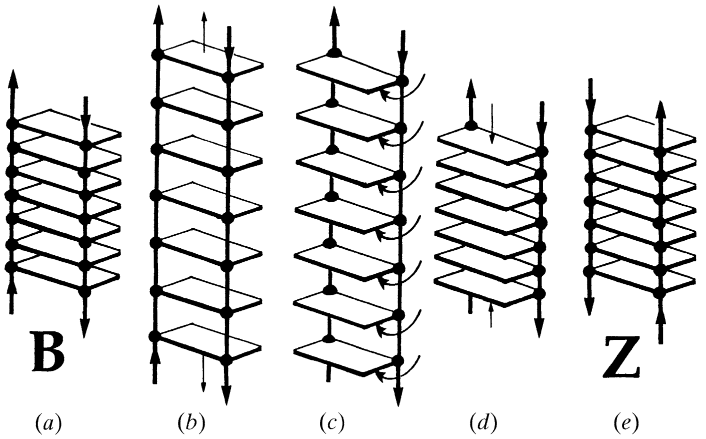

Figure 23.4.3.6
Interconversion of a B to a Z helix. Because the strands have opposite directions in B (*a*) and Z (*e*), interconversion must involve opening up the helix (*b*), flipping each base pair to the other side (*c*), and re-stacking base pairs (*d*). (*d*) and (*e*) are identical upon rotation about a vertical axis.

---

[1] Rich and co-workers (Schwartz *et al.*, 1999) have recently solved the crystal structure of the Zα domain of the human editing enzyme ADAR1 in a complex with a six-base-pair Z-DNA helix of sequence CGCGCG. This left-handed hexamer may suffer from the same length *versus* conformation uncertainty mentioned later in this chapter in connection with oligonucleotide crystals, especially since protein–DNA contacts in the Zα complex occur only with the zigzag phosphate backbone, which is not that dissimilar in Z-DNA (Fig. 23.4.3.3) and Z(WC)-DNA (Fig. 23.4.3.7). Nevertheless, it is encouraging to see a short segment of Z actually making contact with its protein in a presumably biologically relevant context.

edness and a dinucleotide repeat, both shared by Z-DNA and Z(WC)-DNA.

The Z(WC) helix is shown in Fig. 23.4.3.7, and a different stereo view appears as Fig. 7 of Dickerson (1992). Like Z-DNA, it is left-handed, with a deep minor groove and shallow major groove. Cytosines with *anti* glycosyl bonds and guanines with *syn* bonds alternate along each backbone strand. However, sugar puckering is reversed: cytosines are C3′-*endo*, while guanines are C2′-*endo*. In Z-DNA, the backbone chain runs parallel to the helix axis past G, and at right angles to the axis past C. In Z(WC)-DNA, this is reversed: parallel to the helix past C, and at right angles past G. Because of efficient stacking of base pairs, the logical two-base-pair structural unit in Z-DNA is $^{5'}$C–G$^{3'}$; in Z(WC)-DNA it is $^{5'}$G–C$^{3'}$. One such unit is clearly visible in the centre of Fig. 23.4.3.7. This behaviour is reflected in local twist angles:

Helix	C–G	G–C	Sum
Z-DNA	−8°	−52°	−60°
Z(WC)-DNA	−70°	+10°	−60°

The Ansevin–Wang helix has been sedulously ignored since its publication in 1990, especially by crystallographers. The Science Citation Index lists an average of *one* citation of their paper per year since publication, most commonly by spectroscopists. Ho & Mooers (1996) are almost alone among crystallographers in coupling the B-to-Z interconversion dilemma to the possible existence of a different kind of left-handed structure in long polynucleotides. Of course the Z(WC)-DNA structure, as presented here, is only a model; it could be far from the true structure in many respects. But its interest lies in the fact that a left-handed alternating helix with 'standard' backbone directions *can* be built with reasonable bond geometries and with properties that fit the various physical measurements as well as Z-DNA. It calls into question not the correctness of the Z-DNA structure obtained from short oligomers with free helix ends, but the relevance of that structure to the production of left-handed regions in longer duplexes with constrained ends.

23.4.4. Sequence–structure relationships in B-DNA

Two channels of information exist in B-DNA by which base sequence is expressed to the outside world. One of these is the Watson–Crick base pairing of A with T and G with C that is used in the storage of genetic information and in replication and transcription. The other channel, used in control and regulation of the expression of this genetic information, involves the hydrogen-bonding patterns of base-pair edges along the floors of the grooves and any systematic deformations of local helix structure that result explicitly from the base sequence.

The simplest and most direct expression of this second channel is the passive reading of hydrogen-bonding patterns along the floor of the major and minor grooves. This readout mechanism was first proposed by Seeman *et al.* (1976), and involves acceptors and donors as marked by *A* and *D* in Fig. 23.4.2.7. The wide major groove of B-DNA is read by several classes of control proteins that function by positioning an α-helix within the groove so that its amino-acid side chains can sense the pattern of hydrogen bonding. This category includes prokaryotic and eukaryotic helix-turn-helix or HTH proteins, zinc-finger and other zinc-binding proteins, basic leucine zippers and their basic helix-loop-helix cousins, and others (See Table I of Dickerson & Chiu, 1997). The narrower minor groove is a frequent target for long, planar drug molecules, such as netropsin and distamycin, as listed in Part II of Table A23.4.1.2.

In principle, this readout mechanism would work perfectly well with a regular, ideal, fibre-like B-DNA helix. But other control proteins that recognize the minor groove, such as TATA-binding protein (TBP) and integration host factor (IHF), depend not merely on passive hydrogen bonding to an ideally regular duplex, but on the *sequence-dependent deformability* of one region of the helix *versus* another. The remainder of this chapter will be concerned with this effect and its role in DNA recognition.

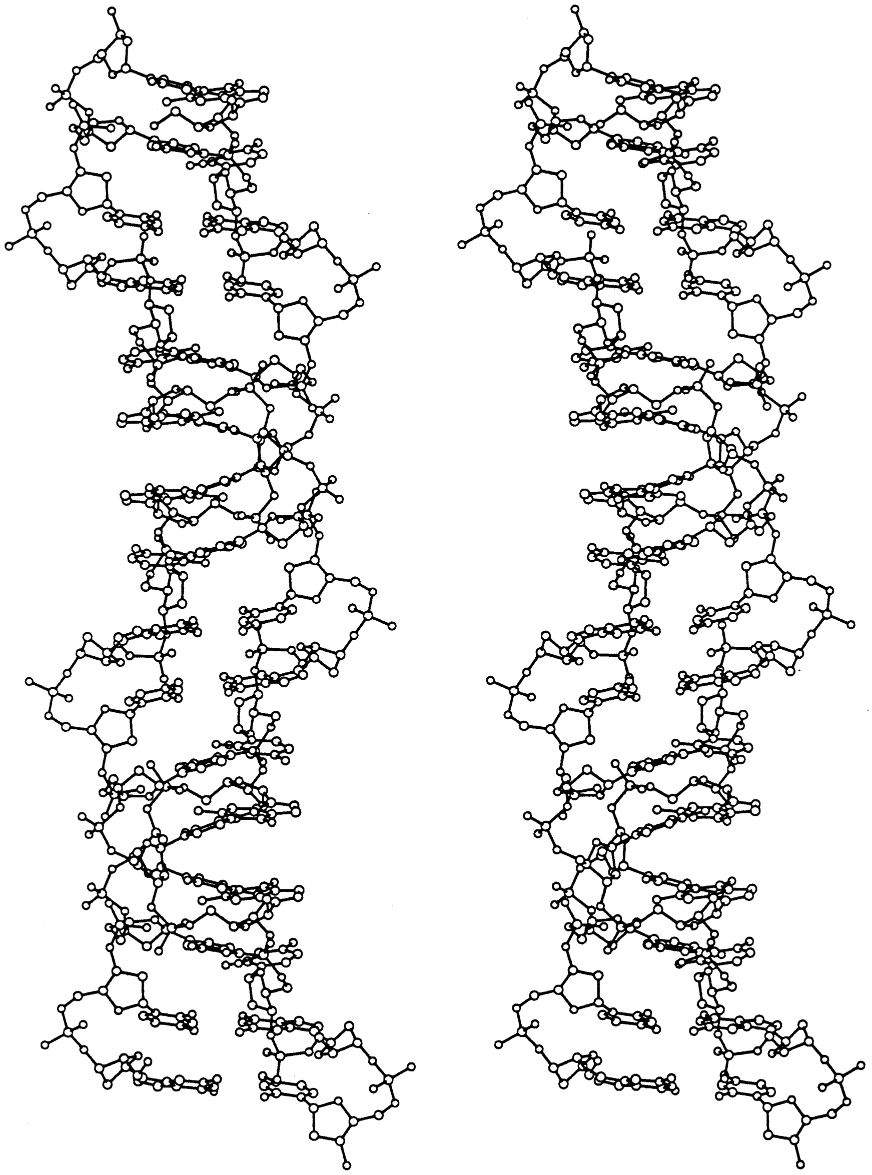

Figure 23.4.3.7
Z(WC)-DNA, or 'Watson–Crick Z-DNA', a proposed left-handed, zigzag, alternating purine/pyrimidine helix with many of the properties of Z-DNA, but with the backbone chain sense found in A- and B-DNA (Ansevin & Wang, 1990). Coordinates courtesy of Allen T. Ansevin.

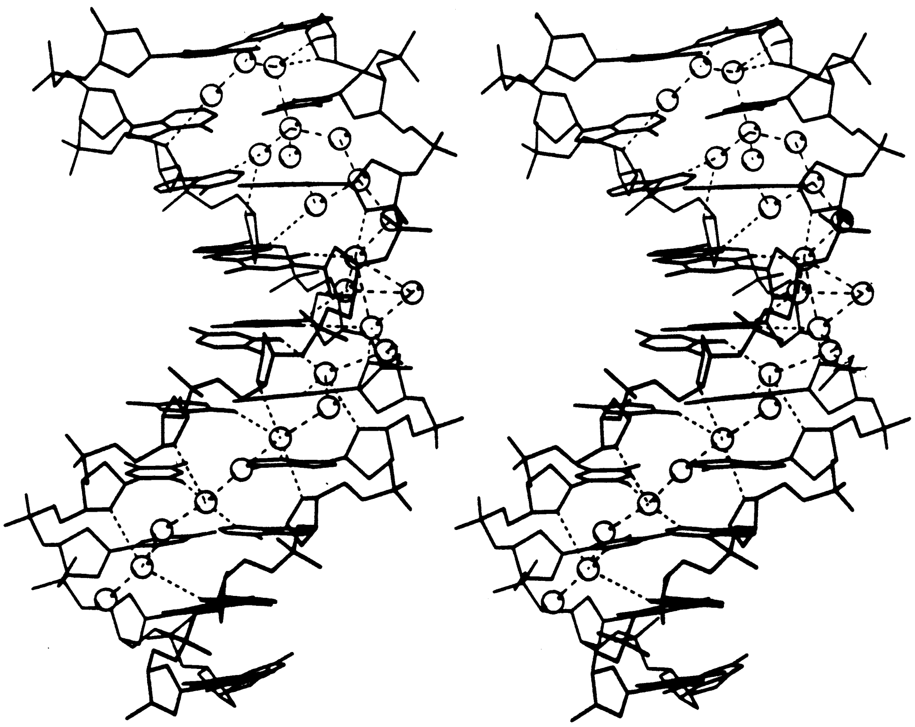

Figure 23.4.4.1
Structure of C-A-A-A-G-A-A-A-A-G (B107). The lower half of the helix, with -A-A-A-A-G, exhibits the narrow minor groove commonly associated with the AT region of the helix and a single zigzag spine of hydration, as was first seen in C-G-C-G-A-A-T-T-C-G-C-G (B1–B6). The upper half, with C-A-A-A-G-, has the wider minor groove of general-sequence B-DNA and two separate rows of hydrating water molecules along the two walls of the wider groove.

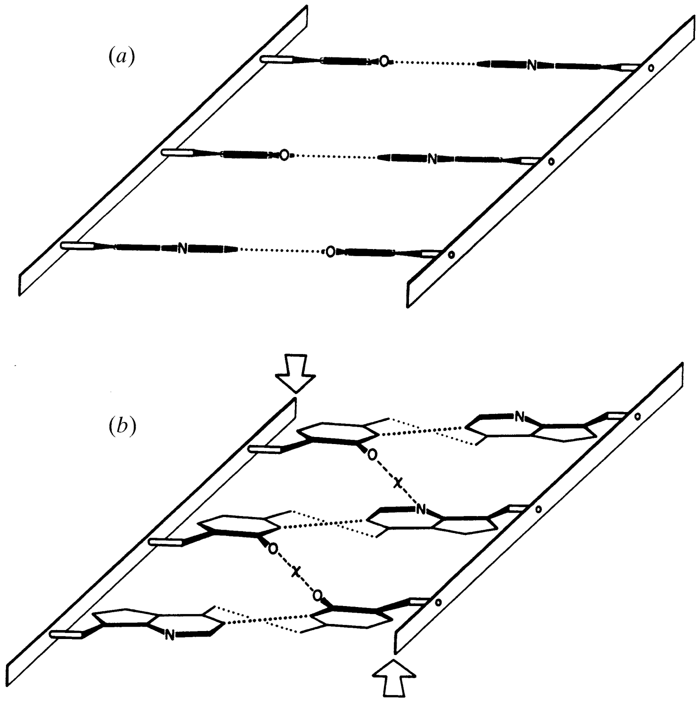

Figure 23.4.4.2
Relationship between minor groove width and propeller twist. (*a*) View into the minor groove of B-DNA, with base pairs seen on edge and with the sugar–phosphate backbones shown schematically as inclined ladder uprights. (*b*) Consequences of propeller twisting the base pairs. Glycosyl bonds connected to sugar C1′ atoms are all displaced upward in the right strand and downward in the left strand. This shifts the backbone chains as indicated by the arrows. Hence, the gap between the chains is decreased, and the minor groove is narrowed.

23.4.4.1. Sequence-dependent deformability

23.4.4.1.1. Minor groove width

The simplest and first-noticed sequence-dependent deformability of the B-DNA duplex was variation in minor groove width. The first B-DNA oligomer to be solved, C-G-C-G-A-A-T-T-C-G-C-G (B1–B6), had a narrow minor groove in the central A-A-T-T region, with only *ca* 3.5 Å of free space between opposing phosphates and sugar rings. (It has become conventional to define the free space between phosphates as the measured minimal P–P separation across the groove, less 5.8 Å to represent two phosphate-group radii. Similarly, the measured distance between sugar oxygens is decreased by 2.8 Å, representing two oxygen van der Waals radii.) The C-G-C-G ends of the helix had the 6–7 Å opening expected for ideal B-DNA, but the situation was clouded, because the outermost two base pairs at each end of the helix interlocked minor grooves with neighbours in the crystal. Hence, the wider ends could possibly be only an artifact of crystal packing.

After 1991, the situation was clarified by the structures of several decamers [Table A23.4.1.2, Part I(*c*)], which stack on top of one another without the interlocking of grooves. The normal minor groove opening is *ca* 7 Å. Regions of four or more AT base pairs can exhibit a significantly narrowed minor groove, although such narrowing is not mandatory. This behaviour is seen with the B-DNA decamer, C-A-A-A-G-A-A-A-A-G, in Fig. 23.4.4.1. The narrowing arises mainly from the larger allowable propeller twist in AT base pairs, which displaces C1′ atoms at opposite ends of the pair in different directions, and moves the backbone chains in such a way as to partially close the groove (Fig. 23.4.4.2).

This is an excellent example of the concept of *sequence-dependent helix deformability*, rather than simple deformation. The two hydrogen bonds of an AT base pair allow a larger propeller twist but do not require it. Hence, AT regions of helix permit a narrowing of the minor groove but do not demand it. Indeed, this lesson was brought home in the most dramatic way when Pelton & Wemmer (1989, 1990) showed *via* NMR that a 2:1 complex of distamycin with C-G-C-A-A-A-T-T-G-G-C or C-G-C-A-A-A-T-T-T-G-C-G could exist, in which two drug molecules sat side-by-side within an enlarged central minor groove. Fig. 23.4.4.3 shows a narrow minor groove with a single netropsin molecule, and Fig. 23.4.4.4 shows a wide minor groove enclosing two di-imidazole lexitropsins side-by-side. In summary, an AT-rich region of minor groove is capable of narrowing but is not inevitably narrow, in contrast to GC-rich regions where the third hydrogen bond tends to keep the base pairs flat and the minor groove wide. The AT minor groove is potentially *deformable* without being inevitably *deformed*.

23.4.4.1.2. Helix bending

Sequence-dependent bendability has been reviewed recently by Dickerson (1988*a*,*b*,*c*) and Dickerson & Chiu (1997). The relative bendability of different regions of B-DNA sequence is an important aspect of recognition, one that is used by countless control proteins that must bind to a particular region of double helix. Catabolite activator protein or CAP (Schultz *et al.*, 1991; Parkinson *et al.*, 1996), *lacI* (Lewis *et al.*, 1996) and *purR* (Schumacher *et al.*, 1994) repressors, $\gamma\delta$-resolvase (Yang & Steitz, 1995), *Eco*RV restriction enzyme (Winkler *et al.*, 1993; Kostrewa & Winkler, 1995), integration host factor or IHF (Rice *et al.*, 1996), and TBP or TATA-binding protein (Kim, Gerger *et al.*, 1993; Kim, Nikolov & Burley, 1993; Nikolov *et al.*, 1996; Juo *et al.*, 1996) are all sequence-specific DNA-binding proteins that bend or deform the nucleic acid duplex severely during the recognition process. IHF in Fig. 23.4.4.5 may be taken as representative of this class of DNA-binding proteins. The bend is produced by two localized rolls of *ca* 60° in a direction compressing the major groove and are additive, because they are spaced nine base pairs, or roughly one turn of helix, apart. In IHF, the two helix segments flanking the bend should be straight and unbent, and this is accomplished in one segment *via* a six-adenine A-tract: -C-A-A-A-A-A-A-G-.

The bending locus in IHF is C-A-A-T/A-T-T-G . It is C-G in *lacI* and *purR* repressors (Fig. 23.4.4.6), C-A = T-G in CAP (Fig. 10 of Dickerson, 1998*b*), and T-A in *Eco*RV, $\gamma\delta$-resolvase and TBP (Fig. 23.4.4.7). Pyrimidine-purine or Y-R steps appear to be especially suitable loci for roll bending. The dashed lines in Figs. 23.4.4.6 and 23.4.4.7 plot tilt, and demonstrate its insignificance in bending, compared with roll. (This is intuitively obvious. Imagine yourself standing near a tall stack of wooden planks in a lumberyard during an earthquake. Where would you prefer to stand: alongside the stack, or at one end?)

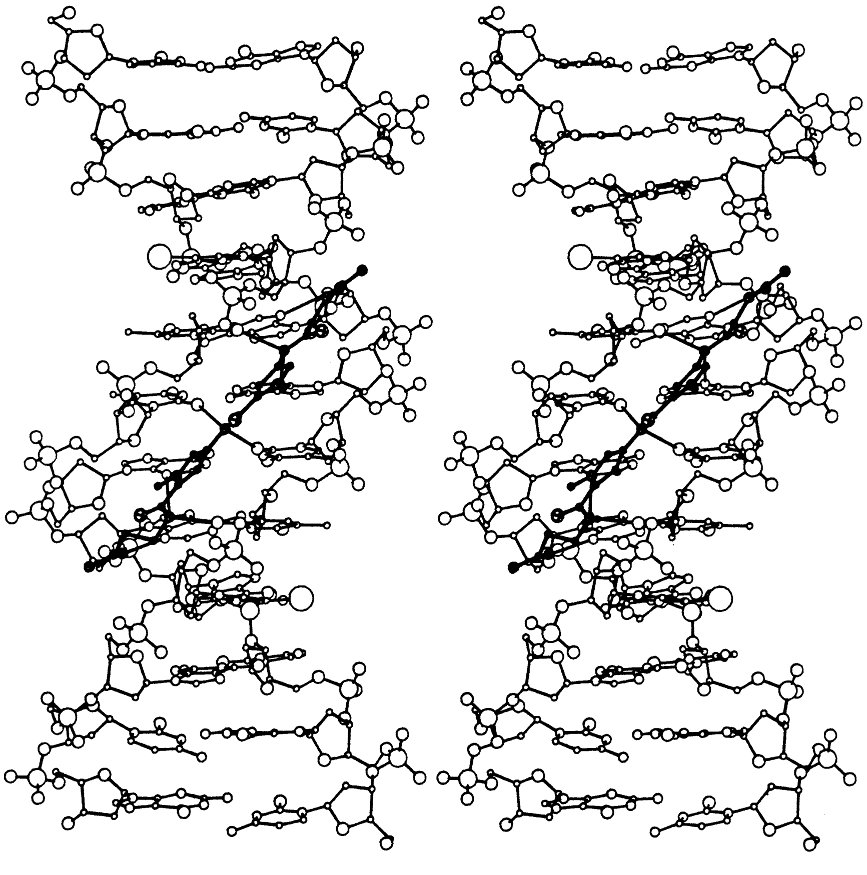

Figure 23.4.4.3
Structure of the 1:1 complex of netropsin with C-G-C-G-A-A-T-T-C-G-C-G (B11, B12, B87). The drug binds to the central -A-A-T-T- region of the minor groove, which is barely wide enough to enclose the nearly planar polyamide molecule. The netropsin structure can be represented by

$$^{+}(NH_2)_2C{-}NH{-}CH_2{-}CONH{-}Py{-}CONH{-}Py{-}CONH{-}CH_2{-}CH_2{-}C(NH_2)_2^{+}$$

where Py is a five-membered methylpyrrole ring. An even more compact representation, useful when comparing other polyamide netropsin analogues or lexitropsins, is $^{+}$=Py=Py=$^{+}$, where the common cationic tails are indicated only by a plus sign, and = represents a —CONH— amide.

In summary, bending of the B-DNA helix nearly always involves roll, not tilt. The easier direction of bending is that which compresses the broad major groove, although examples of roll compression of the minor groove are known. Y-R steps are especially prone to roll bending. Again, the phenomenon is one of sequence-induced bendability, not mandatory bending. No one imagines that the IHF binding sequence of Fig. 23.4.4.5 is permanently kinked at its two C-A-A-T/A-T-T-G steps, wandering deformed through the nucleus, looking for an IHF molecule to bind to. Instead, this sequence has a potential bendability that other sequences, such as A-A-A-A-A-A, lack.

Table 23.4.4.1 summarizes the observed behaviour of Y-R, R-R and R-Y steps from a great many X-ray crystal structure analyses, with and without bound DNA. In the present context, these rules are termed the ‘Major Canon’, since they are well established and generally well understood. Some understanding of the proneness of Y-R steps to bend can be obtained by looking at stereo pairs of two successive base pairs viewed down the helix axis. Fig. 23.4.4.8 gives a few representative examples; many more can be found in Figs. 4–6 of Dickerson (1988*b*) and in the original literature. In brief, Y-R steps, especially C-A and T-A, tend to orient so that polar exocyclic N and O atoms stack against polarizable rings of the other base pair. This is the same type of polar-on-polarizable stacking stabilization mentioned earlier in connection with O4′ and guanine in Z-DNA (Bugg *et al.*, 1971; Thomas *et al.*, 1982; Hunter &

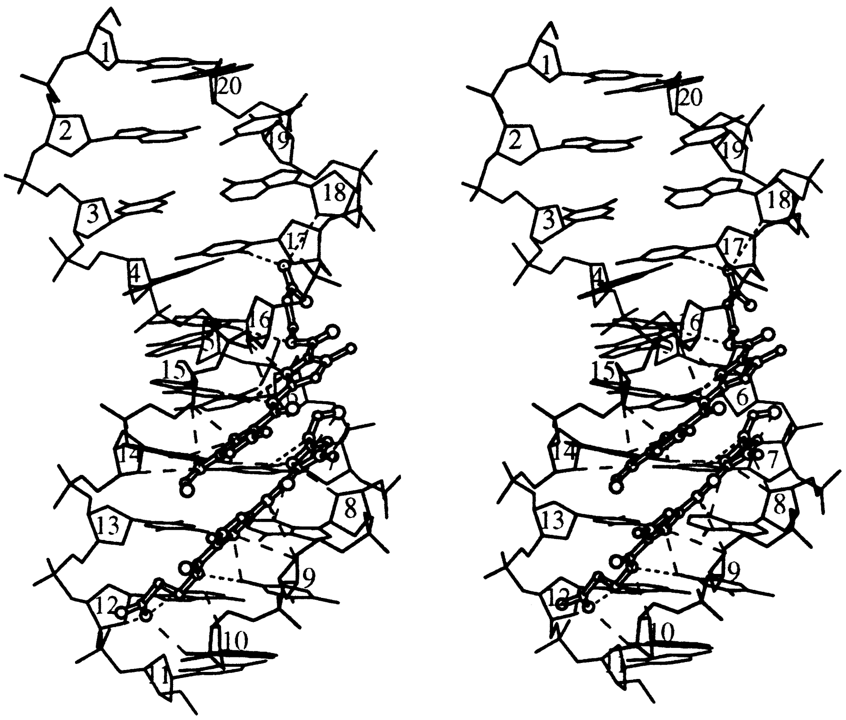

Figure 23.4.4.4

Structure of the 2:1 complex of a di-imidazole lexitropsin with C-A-T-G-G-C-C-A-T-G (B108). The drug now is represented by

$$\text{H–CONH–Im–CONH–Im–CONH–CH}_2\text{–CH}_2\text{–C(NH}_2)_2^+$$

where Im is a five-membered imidazole ring, or again more compactly by ^{0}=Im=Im=$^+$. The uncharged leading amide group, characteristic of distamycins, is identified by ^{0}. Distamycin itself would be represented in this shorthand notation by ^{0}=Py=Py=Py=$^+$. Reprinted from B108, copyright (1977), with permission from Excerpta Medica Inc.

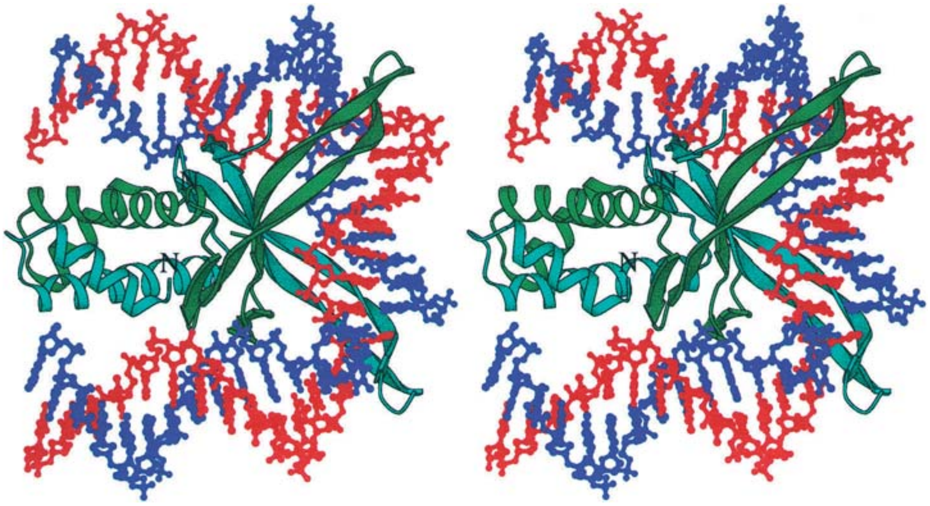

Figure 23.4.4.5

DNA duplex (red and blue strands) looped around IHF or integration host factor. The two subunits of the IHF duplex are green and turquoise. Two antiparallel loops of protein chain, one from each subunit, insert into the minor groove of B-DNA at the sequence C-A-A-T/A-T-T-G and produce abrupt bends *via* local roll angles of 60°. The two localized bends are additive because they occur one helical turn apart. All other steps have roll angles of 5° or less. The two flanking helix segments pack against the IHF dimer and must be kept straight and unbent. This is accomplished in one of the two segments by an A-tract of sequence C-A-A-A-A-A-A-G. From Dickerson & Chiu (1997). Coordinates courtesy of P. Rice.

Sanders, 1990; B32). Base pairs in T-A steps tend not to slide over one another along their long axes, keeping pyrimidine O2 stacked over the purine five-membered ring (Fig. 23.4.4.8*b*). C-A steps can adopt this same stacking, or the base pairs can slide until the pyrimidine O2 sits over the purine six-membered ring instead (Fig. 23.4.4.8*a*).

Purine-purine or R-R steps behave quite differently (Fig. 23.4.4.8*c*). They stack ring-on-ring, usually with greater overlap on the purine end than the pyrimidine. The net effect is that the pivot appears to pass through or near the purines, while pyrimidines at the other end of the pairs stack O2-on-ring as with Y-R steps. R-Y steps tend to stack ring-on-ring, with little contribution from exocyclic atoms.

El Hassan & Calladine (1997) have recently examined roll, slide and twist behaviour at 400 different steps observed in crystal structures of 24 A- and 36 B-DNA oligomers. The author has carried out a similar analysis of 1137 steps from 86 sequence-specific protein–DNA complexes (Dickerson, 1998*a*,*c*; Dickerson & Chiu, 1997). A striking feature is that trends in local parameters are just the same in DNA crystals and in protein–DNA

Sequence-dependent differential deformability in B-DNA. I. The Major Canon

See Dickerson (1998*a*,*b*,*c*) and Dickerson & Chiu (1997).

(1) *Structural basis for helix bending in B-DNA*

Bending is nearly always the result of roll between successive base pairs, seldom tilt.

Positive roll, compressing the wide major groove, is more common than negative roll, in which the narrower minor groove is compressed.

Observed bends in B-DNA are of three main types: (*a*) *localized kinks* (large positive roll at one or two discrete base steps), (*b*) *three-dimensional writhe* (positive roll at a series of successive steps), or (*c*) *smooth curvature* (alternation of positive and negative roll every half turn, with side-to-side zigzagging at intermediate positions). (*a*) and (*b*) are easier to accomplish than (*c*), and hence are more common.

Local writhe in a DNA helix produces macroscopic curvature only when the extent of writhe does not match the natural rotational periodicity of the helix. Endless writhe results in a straight helix, and indeed A-DNA can be regarded as a continuously writhed variant of the B form. Conversely, the bending effect of writhe can be amplified if it is repeated with the periodicity of the helix itself – that is, repeated alternation of writhed and unwrithed segments every ten base pairs, as with A-tract B-DNA.

(2) *Pyrimidine-purine (Y-R) steps: C-A = T-G, T-A and C-G*

Little ring–ring stacking overlap.

Polar N or O stacked over polarizable aromatic rings.

Y-R steps are natural fracture points for the helix. They can show (but are not required in every case to show) large twist and slide deformations, and bending mainly *via* positive roll, compressing the major groove.

(3) *Purine-purine (R-R) steps: A-A = T-T, A-G = C-T, G-A = T-C and G-G = C-C*

Extensive ring–ring overlap.

Base pairs tend to pivot about stacked purines as a hinge, with greater ring–ring separation at pyrimidine ends.

Tight stacking, with only minor roll, slide and twist deformations.

(4) *Purine-pyrimidine (R-Y) steps: A-C = G-T, A-T and C-G*

Behaviour in general like R-R steps, with extensive ring–ring overlap and tight stacking, with again only minor roll, slide and twist deformations.

(5) *A-A and A-T steps, as contrasted with T-A*

Especially resistant to roll bending, probably because of sawhorse interlocking of highly propellered base pairs, supplemented by inter-base-pair hydrogen bonds within grooves. In contrast, T-A is particularly weak and subject to roll bending.

A-tracts, defined as four or more consecutive AT base pairs without the disruptive T-A step, are especially straight and resistant to bending. Natural selection has apparently chosen short A-tracts for regions of protein–DNA contacts where bending is not wanted.

complexes. The frequently invoked nightmare of 'crystal packing deformations' appears to be of only minor significance. In both studies (El Hassan & Calladine, 1997; Dickerson, 1998*b*), roll *versus* slide, slide *versus* twist and twist *versus* roll plots are presented for all ten possible base-pair steps. Fig. 23.4.4.9 illustrates roll *versus* slide plots for two Y-R, two R-R and two R-Y steps.

Table 23.4.4.2 summarizes observations from these roll/slide/twist plots. These are labelled the 'Minor Canon' since they are recent, approximate and not well understood. However, they provide goals for future investigations of helix behaviour.

23.4.4.2. *A-tract bending*

It has long been known that introduction of short A-tracts into general-sequence B-DNA in phase with the natural 10–10.5 base-pair repeat produced overall curvature that could be detected *via* eletrophoretic gel retardation, ring-cyclization kinetics and other physical measurements in solution (Marini *et al.*, 1982; Wu & Crothers, 1984; Koo *et al.*, 1986; Crothers & Drak, 1992). However, the microscopic source of the observed macroscopic curvature remained unclear. Solution measurements alone cannot discriminate between three alternative curvature models: (1) local bending within the A-tracts themselves; (2) bending at junctions between A-tract B-DNA and general-sequence B-DNA; or (3) inherently straight and unbent A-tracts, with curvature resulting from removal of the normal writhe expected in general-sequence B-DNA (Koo *et al.*, 1990; Crothers *et al.*, 1990). The three curvature models are compared schematically in Fig. 10 of reference B77.

X-ray crystallographic results for DNA oligomers come down unequivocally in favour of model (3) above. Short A-tracts of four to six base pairs are straight and unbent in C-G-C-G-A-A-T-T-C-G-C-G (B1–B6), C-G-C-A-A-A-A-A-A-G-C-G (B20), C-G-C-A-A-A-A-A-T-G-C-G (B31), C-G-C-A-A-A-T-T-T-G-C-G (B17, B52), C-G-C-G-A-A-A-A-A-A-G-C (B64) and C-A-A-A-G -A-A-A-A-G (B105) (A-tracts are double-underlined). It has been claimed (Sprous *et al.*, 1995) and disputed (Dickerson *et al.*, 1994, 1996) that the observed straightness of crystalline A-tracts was only an artifact of crystal packing, or of the high levels of methyl-2,4-pentanediol (MPD) used in the crystallization. This concern now is put to rest by the observation that B-DNA packed against a protein molecule in its biological working environment behaves exactly the same as B-DNA packed against other DNA molecules in the crystal, as borne out by the roll/slide/twist studies of El Hassan & Calladine (1997) for DNA and of Dickerson (1998*a*,*b*,*c*) and Dickerson & Chiu (1997) for protein–DNA complexes. Added support has come from recent molecular-dynamics simulations by Beveridge and co-workers (Sprous *et al.*, 1999), who have demonstrated that the duplex of sequence GGGGGGAAAATTTTCGAAAATTTTCCCCCC is severely curved because of a roll kink at the double-underlined central CG step, whereas the duplex GGGGGGTTTTAAAACGTTTTAAAACCCCCC is much less curved because the roll kink at CG is counterbalanced by roll kinks in the opposite direction at the two flanking TA steps. In both cases, A-tracts are straight and completely unbent. (Note that both roll kinks can involve compression of the major groove, as expected, because the kink sites are a half turn of helix apart.)

This similarity of behaviour of DNA in crystals and in protein–DNA complexes should come as no surprise, since the local molecular environments – close intermolecular contacts, partial dehydration, low water activity, low local dielectric constant, high ionic strength, presence of divalent cations – are similar in these two cases and quite different from that of free DNA in dilute

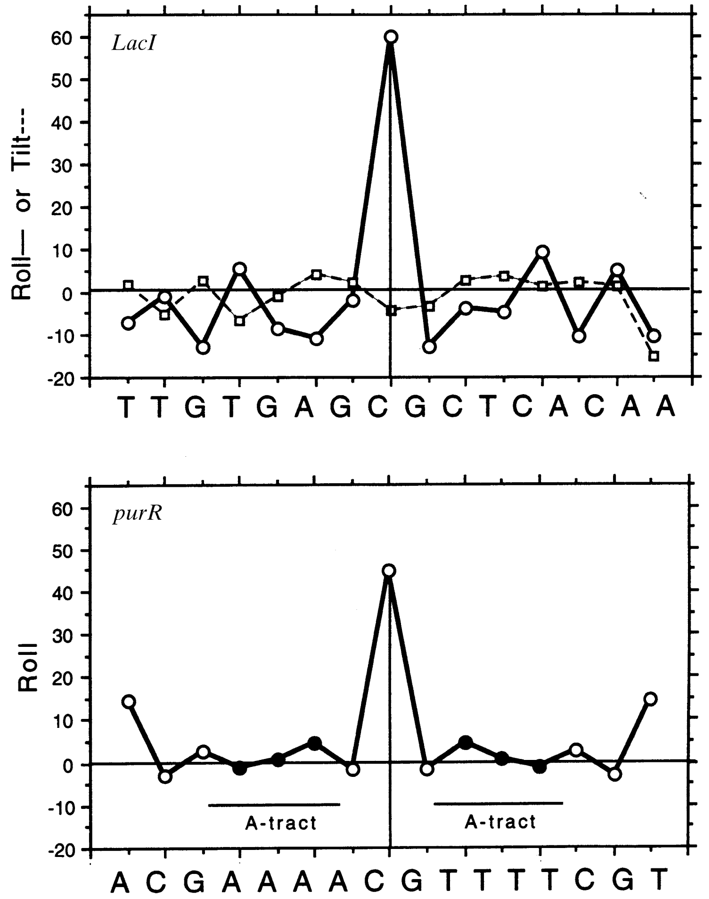

Figure 23.4.4.6
Roll-angle plots for sequence-specific DNA–protein complexes with *lacI* (top) and *purR* (bottom). In each case, bending occurs *via* localized roll at a C-G step. Other steps of the sequence have random rolls of *ca* 10° or less. Note that, as with IHF, A-tracts are especially straight and unbent. Dashed lines in the *lacI* plot demonstrate the unimportance of tilt in production of helix bending.

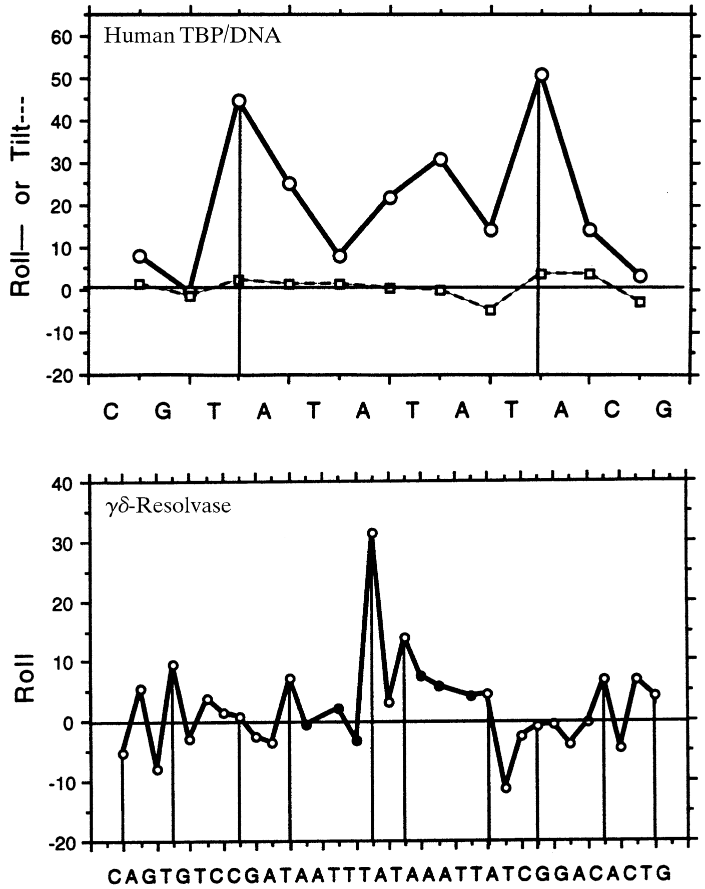

Figure 23.4.4.7
Bending *via* roll at T-A steps in TBP or the TATA-binding protein (top) and in γδ-resolvase (bottom). Note that not every T-A step in TBP or γδ-resolvase is necessarily bent. Note also in γδ-resolvase that C-A = T-G steps, which in proteins such as CAP are used to generate sharp roll bends, here, frequently, are local roll maxima, even though they contribute little to the overall bending. They have a bending *potential* that is not used in this particular setting.

aqueous solution. Far from being unwanted 'crystal deformations', the local changes in structure resulting from intermolecular contacts in DNA crystals provide positive information about sequence-dependent deformability that is relevant to the protein recognition process. With regard specifically to A-tract behaviour, Occam's Razor would argue in favour of model (3) above for the behaviour of A-tracts in solution. The situation in dilute aqueous solution becomes of secondary importance if what is wanted is an understanding of A-tract B-DNA behaviour in protein–DNA complexes. Here, the answer is unambiguous: A-tracts in their biological setting are inherently rigid structural elements, chosen by natural selection when bending should be avoided.

23.4.5. Summary

Three families of nucleic acid double helix have been found – A, B and Z – with widely different structures and usages. The A and B helices are right-handed and have no limitations on base sequence. Z is left-handed and effectively limited to alternating purines and pyrimidines, with G and C overwhelmingly favoured. B is the biologically significant helix for DNA and is used in genetic coding. A is the helix of preference for RNA because it can accommodate the C2′-OH group of ribose, which produces steric clash in the B helix. The Z helix has, as yet, no well established biological function. A left-handed DNA configuration can be induced in longer DNA segments by negative supercoiling in solution, but it is not clear that this left-handed configuration is identical to the Z-DNA seen in short crystalline oligomers, because of the reversed orientation of backbone strands in Z-DNA.

B-DNA is an inherently malleable or deformable duplex. Its sugar ring conformations are much more variable than those of A-DNA. The base sequence of B-DNA is expressed directly *via* hydrogen bonds between bases of a pair, and indirectly *via* hydrogen-bond donors and acceptors along the floor of the major and minor groove. Sequence is also expressed as a *differential deformability* of different regions of the duplex. The two most obvious parameters affected by base sequence are minor groove width and helix bendability. Certain sequences of B-DNA are not statically bent, but are more bendable under stress than are other sequences. Bending occurs *via* roll, usually in the direction that compresses the broad major groove. Pyrimidine-purine or Y-R steps are most conducive to roll bending, and purine-purine steps are least bendable, particularly A-tracts of four or more AT base pairs without the weak T-A step. Natural selection has engineered Y-R steps into a DNA sequence where a sharp roll bend is wanted, and short A-tracts into a sequence where bending is not desired.

Table 23.4.4.2

Sequence-dependent differential deformability in B-DNA. II. The Minor Canon

These generalizations are illustrated by Fig. 23.4.4.9, and are justified at greater length by El Hassan & Calladine (1997) and Dickerson (1998*a*,*b*,*c*).

(6) *Heterogeneous steps ending in A: C-A, T-A and G-A*

Steps ending in adenine, aside from A-A, tend to display (*a*) negative correlation between slide and roll, and between twist and roll, and (*b*) positive correlation between slide and twist.

(7) *Purine-pyrimidine steps*

R-Y steps display, on average, a systematic preference for negative slide and for twist below 36°.

(8) *Relative step frequencies in sequence-specific protein–DNA complexes*

Step A-A is the most common of all, and in 55% of the cases it occurs within A-tracts.

Steps containing only GC base pairs are least common, and seemingly are less compatible with formation of sequence-specific protein complexes.

(9) *Local environment and DNA behaviour*

Sequence-dependent local helix deformations are quite similar in DNA crystals and in protein–DNA complexes. DNA molecules packed against proteins in their normal biological environment appear to have more in common with DNA packed against other DNA helices in the crystal than with free DNA in solution.

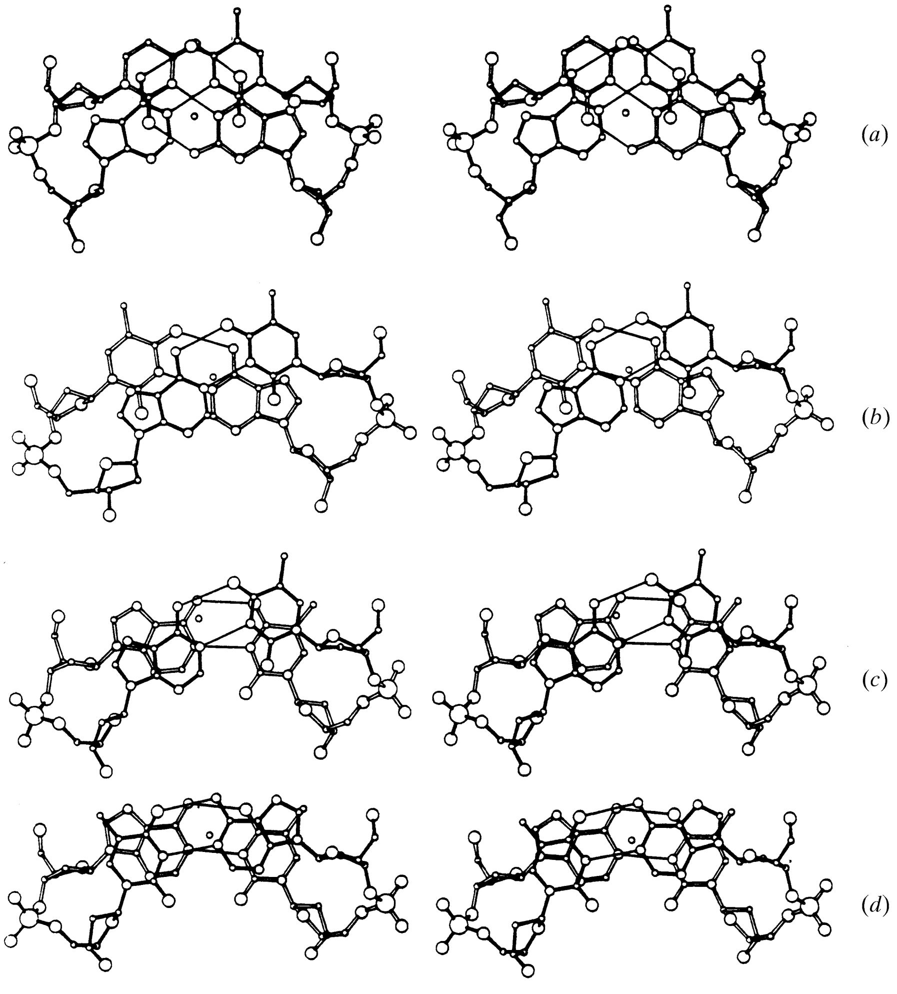

Figure 23.4.4.8

Representative base-pair steps from B-DNA single-crystal X-ray analyses. (*a*) Pyrimidine-purine C-A step from C-C-A-A-G-A-T-T-G-G (B22, B46) (roll/slide/twist = −7.4°/2.6 Å/49.9°). Note the lack of ring-on-ring stacking, replaced by the stacking of pyrimidine O2 and purine N6 or O6, on aromatic rings of the adjacent base pair. This stacking opens up the twist angle to an unusual 50°. Note also the large +2.6 Å slide, which positions pyrimidine O2 over the six-membered rings of the neighbouring purines. (*b*) Pyrimidine-purine T-A step from C-G-A-T-A-T-A-T-C-G (B62) (roll/side/twist = 3.8°/−0.2 Å/39.5°). The stacking is similar to C-A, except that a near-zero slide positions pyrimidine O2 over the five-membered rings of purines. (*c*) Purine-purine A-A step from C-C-A-A-C-G-T-T-G-G (B46, B50) (roll/slide/twist = 8.8°/0.5 Å/28.7°). Ring-on-ring overlap now predominates, with consequently lowered twist angle and essentially zero slide. Note that purines are more extensively stacked than pyrimidines, which appear to be approaching the O2-on-ring stacking of Y-R steps. (*d*) Purine-pyrimidine A-T step from C-G-A-T-A-T-A-T-C-G (B62) (roll/slide/twist = 5.2°/0.0 Å/25.2°). Ring-on-ring stacking again lowers the twist angle and keeps slide around zero. Now there is no stacking of exocyclic N or O on neighbouring rings.

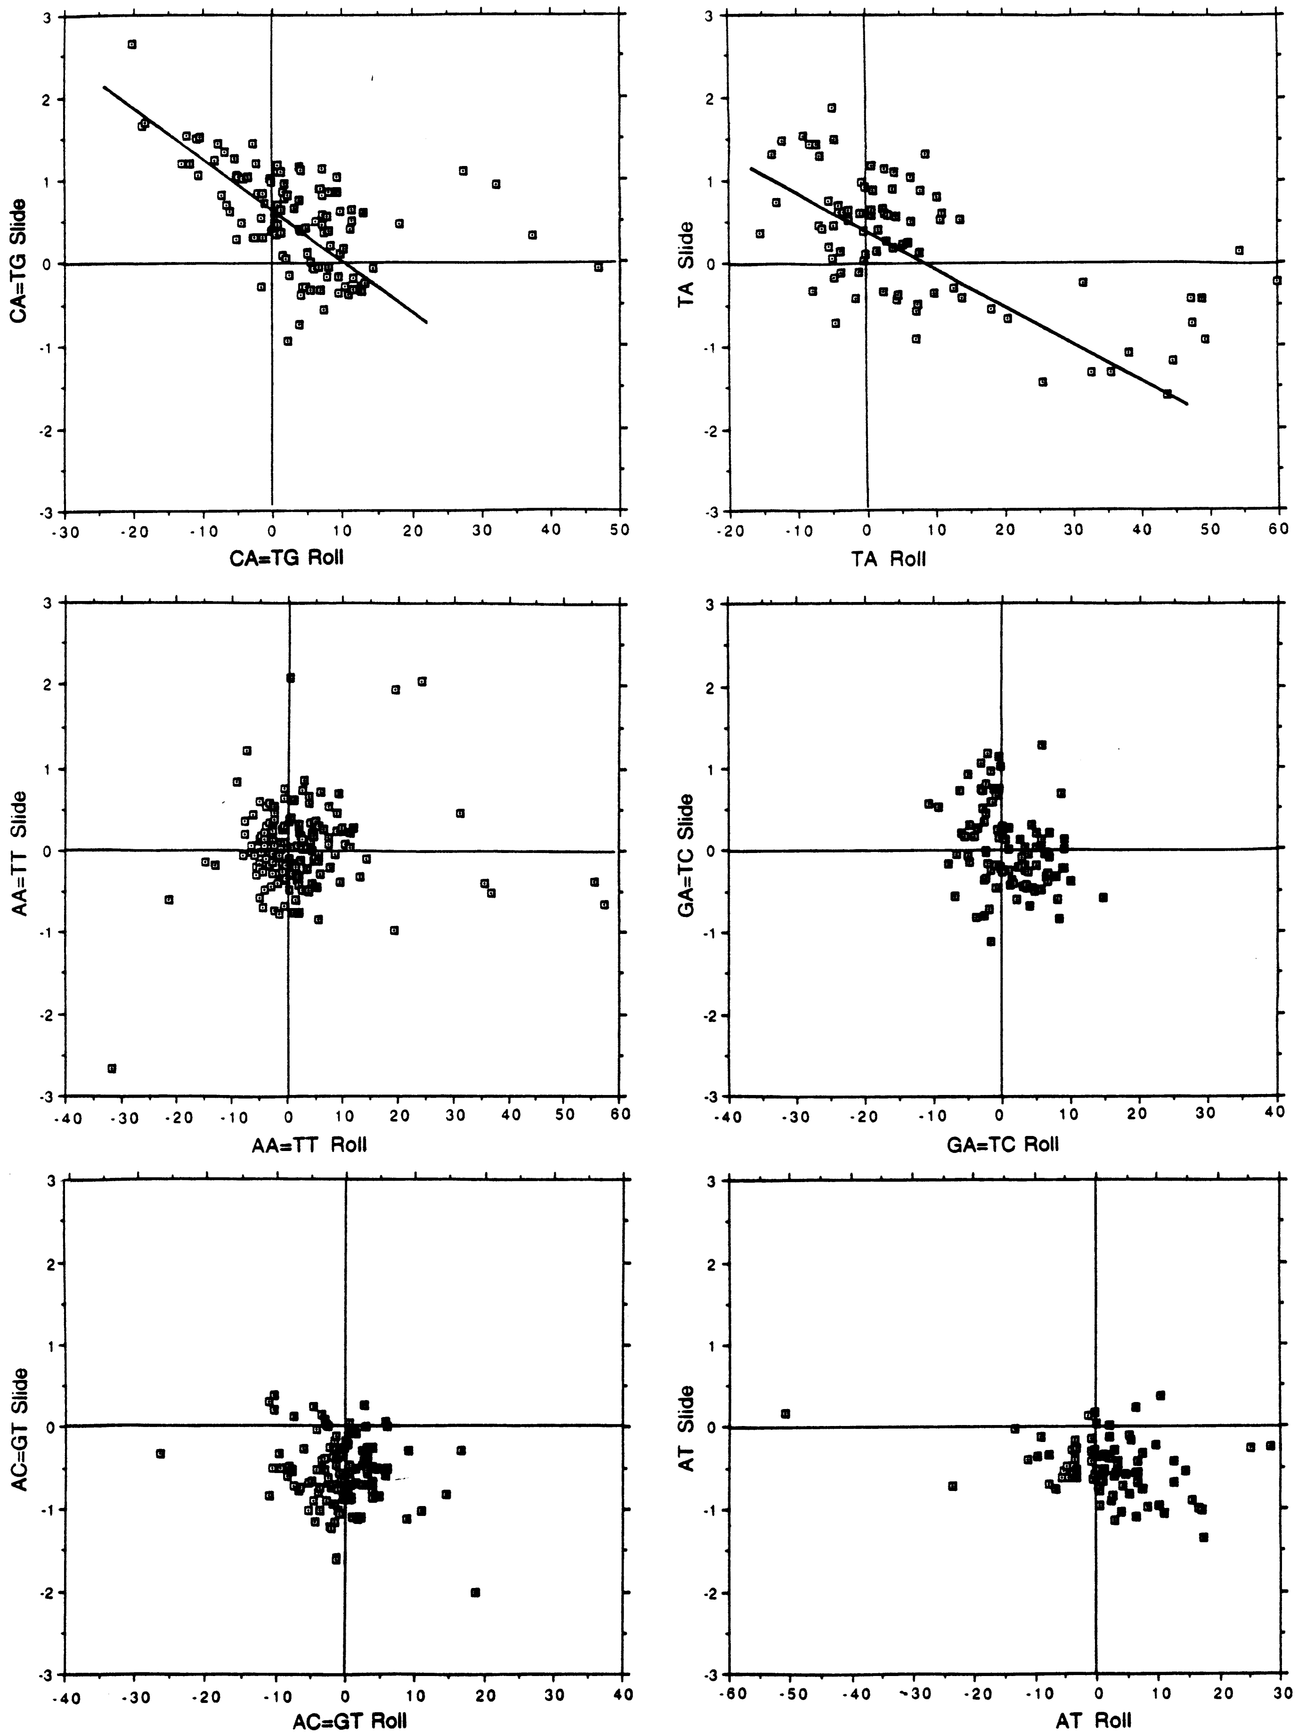

Figure 23.4.4.9

Slide *versus* roll plots for six of the ten possible base-pair steps. Data points are from 971 steps in crystal structure analyses of 63 sequence-specific protein–DNA complexes. A complete set of 30 plots for slide/roll, twist/roll and slide/twist at all ten steps is to be found in Dickerson (1998*b*), and equivalent plots for DNA alone are given by El Hassan & Calladine (1997). Y-R steps exhibit a broad range of roll, slide and twist values, with roughly linear correlations between pairs of variables. Points for A-A and other R-R steps cluster tightly around the origin, showing little tendency toward roll bending. Curiously enough, points for R-Y steps tend to favour negative values of slide and twist, and, hence, to concentrate in the lower left quadrant of a slide/tilt plot.

APPENDIX A23.4.1
X-ray analyses of A, B and Z helices

Table A23.4.1.1
X-ray analyses of A helices, DNA and RNA

This table and the two that follow are intended as a historical background and a focus on the geometry of the intact double helix. References are current as of late 1997; sequences marked 'to be published' in 1997 that still are unpublished two years later have been deleted. Also omitted are sequences with fewer than four base pairs in the asymmetric unit, complexes with intercalating drugs, helices with bulges or looped-out bases, unusual structures such as quadruplexes, hammerhead ribozymes and tRNA. For information on these and for more recent results, consult the Nucleic Acid Database (NDB) at http://ndbserver.rutgers.edu/. An NDB number in parentheses indicates that the authors have never made coordinates available to the public. These structures are of little scientific value, but have been included for historical reasons. Notes: Overhanging, unpaired bases are double underlined. Single underlining calls attention to mismatched bases or other interesting or relevant sequence aspects. Z = number of asymmetric units per cell. Ubp = number of base pairs per asymmetric unit. NDB No. = Nucleic Acid Database serial number. Abbreviations: 2am = 2-amino; 5br = 5-bromo; 6ame = 6′-α-methyl; 4mo = 4-methoxy; 5me = 5-methyl; 6aOH = 6′-α-hydroxyl; 6mo = 6-methoxy; 8oxo = 8-oxo; 6et = 6-ethyl; ara = arabinosyl; ps = phosphorothioate; (P) = leading phosphate; A, T, G, C = DNA; a, u, g, c = RNA; Py = pyrrole; Im = imidazole.

Table A23.4.1.2

X-ray analyses of B-DNA helices and their complexes with minor-groove-binding drug molecules

See introductory notes to Table A23.4.1.1. Space group $P2_12_12_1$ unless specified otherwise.
Notes: (triplet) = external triplet formed from overhanging bases. Overhanging, unpaired bases are $\underline{\underline{\text{double underlined}}}$. $\underline{\text{Single underlining}}$ calls attention to interesting or relevant sequence aspects. Other notes as in Table A23.4.1.1.

I. DNA duplexes without bound drugs

(*a*) Dodecamers, space group $P2_12_12_1$

(1) Oligonucleotides without mismatches

ICATATIC	*C*2	4	4	1997, Ohio State	GDLB49	(B105)

(*b*) Hoechst family

Sequence	*Z*	Ubp	Date, institution	NDB No.	Reference
Hoechst 33258 (*para* -OH on phenyl ring A)					
CGCGAATTCGCG/H	4	12	1987, UCLA	GDL006	(B21)
CGCGAATTCGCG/H	4	12	1988, MIT	GDL002	(B26)
CGCGAATTCGCG/H, 273 K	4	12	1991, UCLA	GDL010,11	(B47)
CGCGAATTCGCG/H, 248 K	4	12	1991, UCLA	GDL012	(B47)
CGCGAATTCGCG/H, 173 K	4	12	1991, UCLA	GDL013	(B47)
CGCGATATCGCG/H	4	12	1989, MIT	GDL007	(B29)
CGCAAATTTGCG/H	4	12	1994, Institute of Cancer Research	GDL028	(B83)
CGCAAATTTGCG/H	4	12	1994, MIT	GDL026	(B84)
CGCGAATTCGCG/H	4	12	1992, Illinois	GDL022	(B60)
CGC^{6et}GAATTCGCG/H	4	12	1992, Illinois	GDLB19	(B60)
Meta-OH(N) Hoechst 33258 (*meta* -OH on ring A)					
CGCGAATTCGCG/H 'in'	4	12	1996, Institute of Cancer Research	GDL047	(B99)
CGCGAATTCGCG/H 'out'	4	12	1996, Institute of Cancer Research	GDL048	(B99)
Hoechst 33342 (*para* -OEt on ring A)					
CGCGAATTCGCG/H	4	12	1992, Illinois	GDLB20	(B60)
CGC^{6et}GAATTCGCG/H	4	12	1992, Illinois	GDLB20	(B60)
Bis-benzimidazole compound (imidazole for piperazine on Hoechst 33258)					
CGCGAATTCGCG/B	4	12	1995, Institute of Cancer Research	GDL033	(B96)
Tribiz or Tris-benzimidazole (extended Hoechst 33258 analogue)					
CGCAAATTTGCG/T	4	12	1996, Institute of Cancer Research	GDL039	(B98)
Bis-amidinium derivative of Hoechst 33258					
CGCGAATTCGCG	4	12	1997, Institute of Cancer Research	GDL052	(B106)

(*c*) Berenil family

Sequence	*Z*	Ubp	Date, institution	NDB No.	Reference
Berenil					
CGCGAATTCGCG/B	4	12	1990, Institute of Cancer Research	GDL009	(B36)
CGCGAATTCGCG/B	4	12	1992, Institute of Cancer Research	GDL016	(B51)
2,5-Bis(4-guanylphenyl)furan (berenil analogue)					
CGCGAATTCGCG/F	4	12	1996, Institute of Cancer Research	GDL036	(B100)
2,5-Bis{[4-(*N*-isopropyl)amidino]phenyl}furan (berenil analogue)					
CGCGAATTCGCG/F	4	12	1996, Institute of Cancer Research	GDL044	(B101)
2,5-Bis{[4-(*N*-cyclopropyl)amidino]phenyl}furan (berenil analogue)					
CGCGAATTCGCG/F	4	12	1997, Institute of Cancer Research	GDL045	(B101)

Table A23.4.1.2 (continued)

(*d*) Other minor-groove binders

Sequence	Space group	*Z*	Ubp	Date, institution	NDB No.	Reference
DAPI						
CGCGAATTCGCG/D		4	12	1989, UCLA	GDL008	(B33)
Pentamidine						
CGCGAATTCGCG/P		4	12	1992, Institute of Cancer Research	GDL015	(B53)
γ-Oxapentamidine						
CGCGAATTCGCG/P		4	12	1994, Institute of Cancer Research	GDL027	(B81)
Propamidine						
CGCGAATTCGCG/P		4	12	1993, Institute of Cancer Research	GDL023	(B71)
CGCGAATTCGCG/P		4	12	1995, Institute of Cancer Research	GDL032	(B92)

Chapter 23.5. Solvent structure

C. Mattos and D. Ringe

23.5.1. Introduction

The unique properties of water and its role in nature have preoccupied the minds of scientists and philosophers for centuries. However, only relatively recently have the tools become available to study the specific roles that water molecules play with respect to protein structure and function. When the first crystal structure of a protein was obtained by X-ray diffraction (Kendrew, 1963), the focus was on the arrangement of the amino-acid residues into secondary and tertiary structure. Although the presence of water molecules associated with the protein was noticed, little attention was given to their structure and possible functional role. The structure of the protein itself was a great novelty, and its features were eagerly analysed. For many years, the crucial role of water molecules in maintaining both the structural integrity and the functional viability of proteins was not completely obvious, although in the 1950s Kauzmann argued correctly that water plays an important role in maintaining protein structure (Kauzmann, 1959). In the late 1970s and early 1980s, reviews began to appear focusing on the properties of water relevant to interaction with proteins (Edsall & McKenzie, 1978) and the location and role of water molecules on protein surfaces (Blake *et al.*, 1983; Edsall & McKenzie, 1983). As high-resolution structures became more easily attainable and refinement techniques improved, the importance of water molecules became increasingly apparent, and solvent structure now occupies a front seat in the realm of structural biology. There is a strong sense in the scientific community that water molecules play an integral role in many aspects of protein structure and function, and great effort is now being focused on understanding solvent effects in precise atomic detail.

In principle, water molecules can contribute both enthalpically and entropically to any process in which they are involved. The main contribution of water as solvent in the protein-folding process, for example, is entropic, driving the collapse of hydrophobic residues into the core of the protein. As is currently understood, the general shape of globular proteins is attained by this effect, with the specific structural features guided by the hydrogen bonds that define secondary structure (Hendsch & Tidor, 1994; Hendsch *et al.*, 1996). Although the solvent contribution to the protein-folding process is beyond the scope of this chapter, its essential role has been recently reviewed elsewhere (Mattos & Clark, 2008). It is important to understand protein three-dimensional structures as having evolved in bulk water, a fact which is largely invisible to the current methods in structural biology. The size, geometry, planarity and orientational flexibility of water molecules give them structural and functional importance. All folded globular proteins have evolved with tens to hundreds of binding sites specific for water molecules, a situation contrary to that of larger ligands which usually bind in a single or small number of specific sites found in a given protein or family of proteins. In this respect, water is unique and its ubiquitous appearance is not a direct consequence of its chemical properties alone, but has an evolutionary origin. Proteins evolved in an aqueous milieu, where over time some water molecules were specifically incorporated as integral parts of the protein architecture.

At first glance, the surface of a protein determined by X-ray crystallography appears randomly populated by a layer of water molecules. A careful analysis, however, reveals that the arrangement of water molecules on protein surfaces is not random. In folded proteins, individual water molecules participate in a variety of structural and functional roles, ranging from filling small cavities that are not fully occupied by protein atoms to allowing flexibility, such as in the case of charged surface side chains that can move freely while continuously maintaining hydrogen-bonding partners. Water molecules can fill deep crevices on the protein surface, or they can play a crucial role in the thermodynamics of ligand binding. The mobility as well as the number and strength of hydrogen-bonding partners that are observed for water molecules bound to protein surfaces vary considerably, and it is becoming increasingly apparent that these factors are correlated with functional roles. The atomic coordinates for any protein should not be considered complete without those bound solvent molecules that can be observed, for they are part of the structure.

Bound water molecules have been implicated and studied in the context of substrate specificity and affinity (Quiocho *et al.*, 1989; Herron *et al.*, 1994; Ladbury, 1996), catalysis (Privé *et al.*, 1992; Singer *et al.*, 1993; Komives *et al.*, 1995), mediation of protein–DNA interactions (Clore *et al.*, 1994; Shakked *et al.*, 1994; Morton & Ladbury, 1996), cooperativity (Royer *et al.*, 1996), conformational stability (Bhat *et al.*, 1994), and drug design (Poormina & Dean, 1995*a*,*b*,*c*). One of the challenges now is to translate the structural information observed into a thermodynamic understanding of the water contribution to the various processes. In some cases, an attempt has been made to relate changes in water structure between two forms of a protein (*e.g.* ligated and unligated or native and mutant) to changes in the measured heat capacity (Holdgate *et al.*, 1997) or to measurements of enthalpy and entropy changes by titration calorimetry (Bhat *et al.*, 1994). Thermodynamic solvent isotope effects have also been reported, where the thermodynamics of association of several binding processes were evaluated calorimetrically in light and heavy water (Chervenak & Toone, 1994). In other cases, the three-dimensional structures were directly interpreted in terms of thermodynamic contributions (Quiocho *et al.*, 1989; Morton & Ladbury, 1996). Ultimately, a thorough understanding of the thermodynamics and kinetics underlying solvent structure will lead to powerful predictive methods. Theoreticians, on the one hand, have developed models based on physical principles and use experimental knowledge to assess whether their predictions are correct. Experimentalists, on the other hand, attempt to explain the observed phenomena in terms of the well established physical theories that govern the natural world. Progress is being made on both fronts, but a large gap still remains between the two. A bridge is being built from both sides of the gap and when the two sides meet at a common point, the many pieces of this complicated puzzle will have been deciphered and put in their proper places, so that a global view of molecular processes in

Copyright © 2012 International Union of Crystallography

water can be obtained from whatever perspective one wishes to take: chemical, physical or biological.

The present chapter summarizes the empirical information gathered over the years on the structure of water molecules bound to proteins. The focus will be on structures solved by X-ray crystallography, although complementary techniques of obtaining solvent structure will be discussed briefly and, when appropriate, particular examples will be given. Section 23.5.2 is concerned with the methods by which solvent structure can be observed, Section 23.5.3 summarizes knowledge derived from database analysis of large numbers of proteins, Section 23.5.4 focuses on particular examples of groups of well studied protein structures, Section 23.5.5 discusses the contribution of protein models obtained at very high resolution to the understanding of solvent structure, and Section 23.5.6 contains an analysis of water molecules as mediators of complex formation. Finally, Section 23.5.7 presents a conclusion and a perspective regarding the direction in which this information can lead in building a cohesive understanding of the roles played by solvent in the structural integrity and biological function of macromolecules.

23.5.2. Determination of water molecules

The most prominent method by which the structure of water molecules on the surface of macromolecules can be observed at the atomic level is X-ray crystallography. The information classically available from this methodology is on bound water molecules, characterized by a high probability density and reduced mobility relative to the bulk solvent, which results in clearly observed electron density. Information on water structure at larger distances from the protein is available in the low-resolution reflections, but this information is more difficult to capture. This chapter focuses on the water molecules for which there is information at high resolution (>3 Å), although great progress has been made in recent years in modelling the disordered water structure at the protein–solvent interface, enabling more effective use of the low-resolution data (Badger, 1993; Jiang & Brünger, 1994; Lounnas *et al.*, 1994). Typically, one is interested in studying solvent structure because of the effects that it has on the protein. Lounnas *et al.* (1994) gave a particularly interesting focus on the effect of the protein on the solvent structure surrounding it. Using a combination of molecular-dynamics simulations of explicitly solvated myoglobin and the low resolution X-ray data from myoglobin crystals, they devised a method to describe the effect of the protein on the solvent structure to a distance of 6 Å from the surface. They found that the mobility and probability density of water molecules perpendicular to the protein surface varied considerably depending on the particular composition and three-dimensional structure of the amino-acid residues at the particular area of interest (Lounnas & Pettitt, 1994; Lounnas *et al.*, 1994).

There are a variety of criteria that have been used in placing crystallographic water molecules in electron-density maps. For tightly bound water molecules, with low *B* factors, the placement involves little or no subjectivity, but the choice of whether or not to include the more disordered waters (or those with low occupancy) can be rather subjective. It generally involves picking the electron-density contour level and *B*-factor cutoffs as well as making a choice of whether to use a simple difference electron-density map ($F_o - F_c$) or to use a higher-order difference electron-density map ($2F_o - F_c$ or $3F_o - 2F_c$). One criterion, applied consistently in placing water molecules on the surface of elastase structures, is the simultaneous presence of electron density at the 3σ contour level in an $F_o - F_c$ electron-density map and at the 1σ contour level in a $2F_o - F_c$ electron-density map. After refinement, those waters are kept that have a *B* factor of 50 Å^2 or less. A few exceptions do occur, where there is clear electron density for a water molecule with a *B* factor of up to 60 Å^2. Virtually all of the water molecules placed by these criteria have at least one hydrogen bond to a protein atom or to another water molecule and are mainly part of the first hydration shell on the protein surface.

A method that has provided information on solvent structure complementary to that obtained by X-ray crystallography is based on $D_2O - H_2O$ neutron difference maps (Shpungin & Kossiakoff, 1986). The main advantage of this methodology is in locating partially ordered water molecules whose electron-density peaks may be at the limit of the signal-to-noise ratio allowed for confidently determining positions of water molecules by X-ray diffraction. Scattering of neutrons by H_2O and D_2O is quite different, while scattering from the protein remains the same. Therefore, difference maps based on the two data sets should average to zero where the protein is present and result in peaks only where water molecules are found. Neutron scattering is particularly suited to this because of the threefold greater scattering power of deuterated water molecules relative to light water, providing a larger signal-to-noise ratio in assigning water positions. This method is particularly useful in detecting the second hydration sphere on protein surfaces (Kossiakoff *et al.*, 1992).

NMR spectroscopy can also serve as a complementary technique, providing dynamic information on the lifetime of interaction of a single water molecule on the protein surface. The fact that, with few exceptions, no cross-relaxation peaks are observed at the protein–water interface is an indication that the motion timescale for water molecules in contact with protein is close to that in bulk water at room temperature. The NMR data suggest that water molecules observed in crystal structures have lifetimes of the order of tens of nanoseconds or less (Bryant, 1996). A small number of relatively long-lived structural waters (with residence times in the range 10^{-2} to 10^{-8} s) can be detected by modern NMR techniques (Otting *et al.*, 1991). Four water molecules have been detected by NMR in bovine pancreatic trypsin inhibitor (BPTI) (Otting & Wuthrich, 1989) and six have been observed in complexes of human dihydrofolate reductase with methotrexate (Meiering & Wagner, 1995). Observation of these waters in the corresponding crystal structures reveals that they are tightly bound waters, with three or four hydrogen bonds to protein atoms, and many are found to bridge between secondary-structure elements or are found to mediate protein–ligand interaction (Meiering & Wagner, 1995). It is important to understand, then, that water molecules near protein surfaces occupy energy minima favoured by hydrogen bonding and ion–dipole effects, which results in water molecules being present in these positions more often than in others. Although when looking at a crystallographic protein structure it is easy to think of a given site as being occupied by a single water molecule, it is in fact only the site that is single, with an enormous number of different individual water molecules sampling it during the time of data collection. This was qualitatively understood from the beginning, but NMR experiments have played a key role in setting quantitative upper boundaries to the residence times of water molecules on the protein surface.

Finally, mention must be made of the computational efforts invested in representing and understanding solvent structure on macromolecular surfaces. The computational work encompasses a variety of methodologies, including integral equation methods (Beglov & Roux, 1997), molecular dynamics (Brooks & Karplus, 1989; Hayward *et al.*, 1993; van Gunsteren *et al.*, 1994), thermodynamic understanding through free-energy simulations (Roux *et al.*, 1996) and statistical-mechanics calculations (Lazaridis *et al.*, 1995). The results of these studies are often complementary to the experimental information already available and provide an important component to the current insight on solvent structure (McDowell & Kossiakoff, 1995) and function (Pomes & Roux, 1996; Oprea *et al.*, 1997). Furthermore, these techniques often provide the only means of obtaining an energetic understanding of some aspects of protein–water interaction.

The question of how the different techniques used to observe the location and properties of water molecules on the surface of proteins relate to and complement one another has been discussed in two short review articles (Levitt & Park, 1993; Karplus & Faerman, 1994). Karplus & Faerman discuss the reliability of each of the methods, illustrating their strengths and weaknesses, while Levitt & Park present the state of our understanding of protein–water interactions as it was in 1993, based on the synthesis of results obtained from the various methods discussed above.

23.5.3. Structural features of protein–water interactions derived from database analysis

The location and nature of water interaction with protein atoms are of great interest for understanding the role played by water molecules in the structural integrity and function of macromolecules. Baker & Hubbard (1984) presented an extensive analysis of hydrogen bonding in 15 proteins. A good portion of the study focused on hydrogen bonding with water. They observed that, in general, hydrogen bonds have a certain degree of flexibility, ranging in distance between 2.4 and 3.4 Å, with angular deviation from linear of up to 60°. The authors discussed the hydrogen-bonding geometry of water itself as well as the general aspects of the hydration of protein groups. Along the protein backbone, each carbonyl group is capable of making two hydrogen bonds, while amido groups make only one. Bifurcated hydrogen bonds are relatively rare, comprising only about 4% of the main-chain amido groups and even fewer of the side chains. Baker & Hubbard (1984) observed that of all of the hydrogen bonds made by water molecules, 42% are to main-chain carbonyl oxygens, 14% to main-chain amide groups and 44% to side-chain atoms. In a subsequent review that surveyed protein–water interactions, Savage & Wlodawer (1986) pointed out some of the major problems that hinder the accurate study of the precise hydrogen-bonding geometry and chemical features of protein–water interactions: the size of the biomolecular system, the resolution of the data, and the disorder of both the biomolecule and the solvent. The review was based on a comparison of X-ray and neutron diffraction studies of water interactions in a handful of proteins solved to a resolution of 1.5 Å or better with hydration properties in crystals of small- and medium-sized molecules solved to better than 1.0 Å resolution. Although a great deal had been learned about hydrogen-bonding properties of water in crystals of small molecules that presumably can be transferred to analogous interactions with protein atoms (Savage, 1986), the authors pointed out that for biomolecules there was, at the time, no consistent method being used for solvent analysis (Savage & Wlodawer, 1986). This problem was demonstrated and analysed in a subsequent review, where a comparison of three independently solved structures of interleukin-1 reveals a large variability in solvent structure (Karplus & Faerman, 1994).

The growing number of high-resolution protein crystal structures currently available in the Protein Data Bank (Berman *et al.*, 2000) allows for studies that extract statistically significant trends specific to protein–water interactions. The analysis of where and how water molecules bind to protein surfaces can be made at different levels. One can look at general properties of water interacting with each of the 20 amino-acid side chains, as well as with main-chain carbonyl oxygens and amido nitrogen atoms. At a higher level, one can study how these local interactions are modulated by the secondary-structure elements in which the residues are found. At the tertiary-structure level, one can study the location and function of water molecules as they are found in bridging secondary-structure elements and their role in the integrity of the protein architecture. At this level, studies regarding surface shape and hydrophilicity become important components of the analysis. Finally, the role of water molecules can be studied at the level of mediating protein–protein and protein–ligand interaction and their function in the affinity and specificity of these interactions. The remainder of this section summarizes information from database analysis of protein–water interactions at these various levels. The following sections then focus on individual examples to illustrate the classifications and functions of water–protein interactions.

23.5.3.1. Water distribution around the individual amino-acid residues in protein structures

The most comprehensive study of water molecules at the local level of binding to the individual types of amino-acid residues in protein structures was published in a series of papers (Thanki *et al.*, 1988, 1990, 1991; Walshaw & Goodfellow, 1993). The initial database consisted of 16 protein structures solved to better than 1.7 Å resolution and refined to an R factor of 26% or better (Thanki *et al.*, 1988). It was subsequently increased to 24 proteins using the same selection criteria (Thanki *et al.*, 1990, 1991; Walshaw & Goodfellow, 1993). All equivalent side chains as well as carbonyl or amide groups present in the database were brought to a common reference frame constructed from previously established bond lengths and bond angles (Momany *et al.*, 1975). The distribution of water molecules interacting with each of the 20 types of side chains was studied by focusing on particular atoms. Therefore, water molecules within 3.5 Å of N and O polar side-chain or main-chain atoms or within 5.0 Å of apolar side-chain carbon atoms were appropriately translated to the reference frame.

Fig. 23.5.3.1 shows the results of these superpositions for the polar main-chain amido and carbonyl groups as well as for some representative polar side chains: Ser, Tyr, Asp, Asn, Arg, His, Trp and Ala. The overall results show that despite the complex protein architecture, water molecules interact with hydroxyl, carbonyl and amide moieties, as well as with the sp^3-hybridized and ring nitrogen atoms, as expected from their known stereochemical requirements (Baker & Hubbard, 1984). Thus, there are water clusters in positions that optimize interaction with the lone-pair electrons on oxygen atoms and with the hydrogen atoms of amide and hydroxyl groups. Figs. 23.5.3.1(*a*) and (*b*) show the distribution of water molecules around the main-chain carbonyl oxygen and amido nitrogen atoms, respectively. The stereochemical requirements mentioned above are satisfied, with the distribution around the carbonyl oxygen clustered in two distinct regions peaking at an O–O distance of 2.7 Å. In contrast, there is

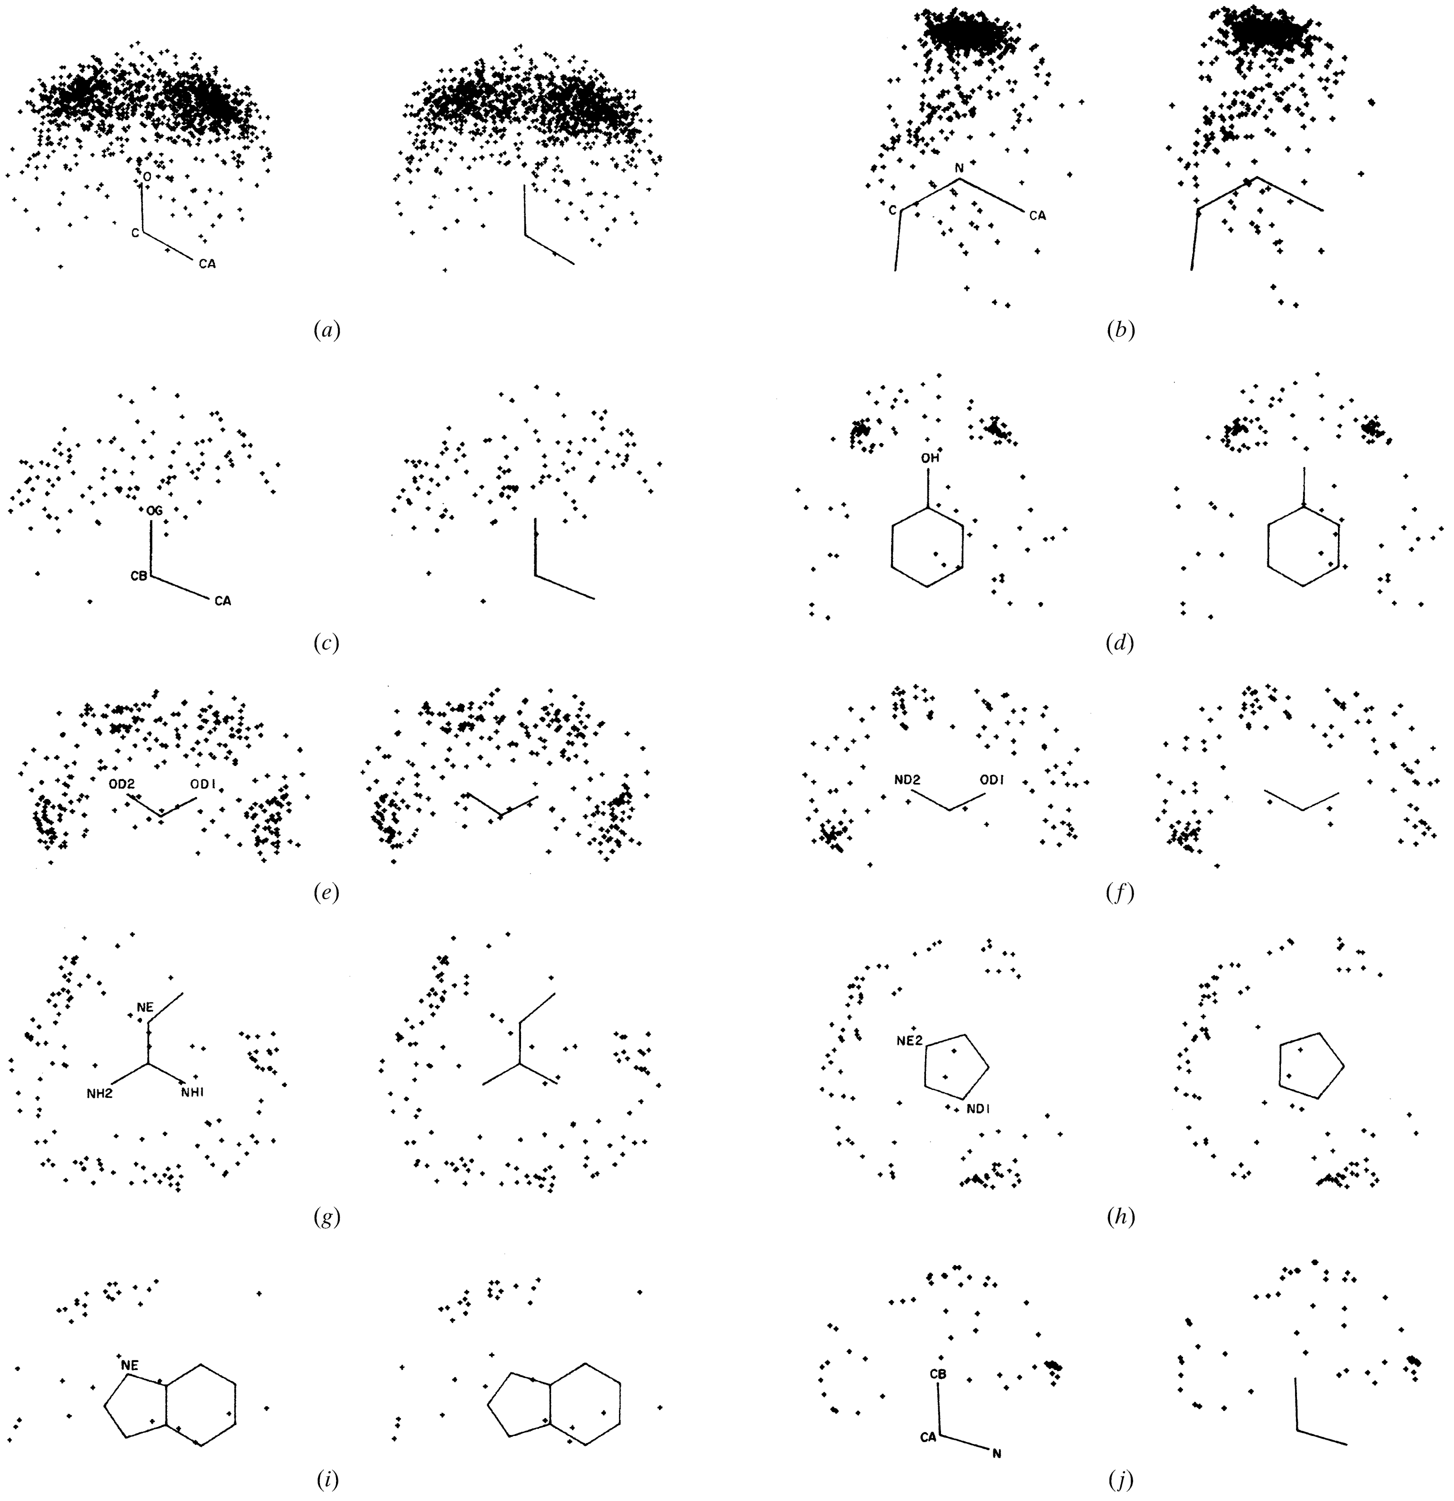

Figure 23.5.3.1

Distribution of water-molecule sites in stereo around: (*a*) main-chain O, (*b*) main-chain N, (*c*) Ser OG, (*d*) Tyr ring, (*e*) Asp OD1 and OD2, (*f*) Asn OD1 and ND2, (*g*) Arg NH1, NH2 and NE, (*h*) His ring to 3.5 Å, (*i*) Trp ring to 3.5 Å, (*j*) Ala CB. a single water cluster interacting with the nitrogen, in line with the N—H bond at an N–O distance of about 2.9 Å. This cluster is much tighter than seen for the interactions with oxygen, reflecting a greater flexibility of water interaction with the carbonyl oxygen relative to the amido-group nitrogen atom.

Ser and Thr residues present a wide distribution of water molecules around the hydroxyl groups, presumably due to the freely rotating side chain. Fig. 23.5.3.1(*c*) shows the water-molecule distribution around Ser, which is only slightly different from that for Thr and can be representative of both. In contrast, the Tyr hydroxyl group is involved in resonance stabilization with the aromatic ring and, consequently, water molecules are clustered in the plane of the ring in well defined positions (Fig. 23.5.3.1*d*).

Fig. 23.5.3.1(*e*) shows the clustering of water molecules around the Asp side chain into four distinct groups, corresponding to the four available lone-pair electrons. The distribution around Glu is similar. Most water molecules interact with a single carbonyl oxygen, although about 11% (for Asp) and 15% (for Glu) of water molecules around these side chains interact with both oxygen atoms of a single carboxyl group. Water molecules that interact with Asn and Gln also show four clusters, with the two

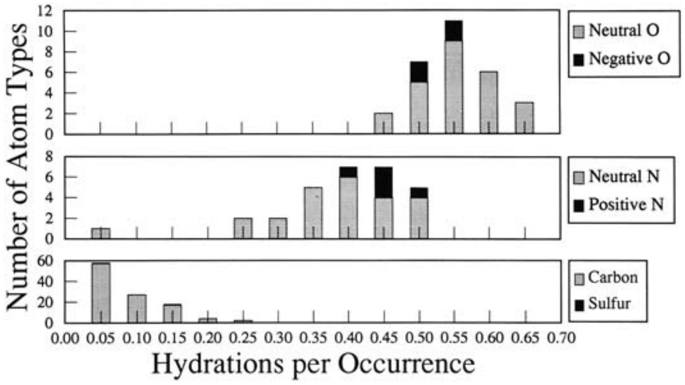

Figure 23.5.3.2

Distribution of atomic hydration values. To determine which atoms are similar or distinct with respect to water binding, we plotted the number of atom types (*e.g.* Ala amide nitrogen, Ala Cα, . . .) at each hydration per occurrence value. Each atom type contributed one vertical unit to the graph. Oxygen atoms were the most hydrated (top graph), with negatively charged oxygen (black bars) slightly less hydrated on average than neutral oxygen (grey bars). Nitrogens (middle graph) were the next most hydrated, overlapping the oxygen distribution, and positively charged nitrogens (black bars) were somewhat more hydrated than neutral nitrogens (grey bars). Proline's amide nitrogen, with no hydrogen-bonding capacity, had the lowest nitrogen hydration value (leftmost bar). Carbon and sulfur atoms (bottom graph; note change of *y*-axis scale) were the least hydrated, with sulfur values at 0.05 and 0.15 hydrations per occurrence. Reproduced from Kuhn *et al.* (1995). clusters around the carbonyl group (C=O) less distinct than those around the amido (NH_2) group. Fig. 23.5.3.1(*f*) shows the distribution of water-molecule sites around Asn. In the case of Gln, the difference in water clustering around the carbonyl and amido groups is much less pronounced, possibly due to a greater degree of confusion in placing this longer side chain in the correct orientation. About 6% of the water molecules that interact with Asn or Gln are involved in hydrogen bonding to both the carbonyl oxygen and the amido nitrogen atoms.

The clustering of water molecules around the planar guanidyl group of Arg is distinctly positioned around the Nε atom and on either side of the NH1 and NH2 atoms. This is shown in Fig. 23.5.3.1(*g*). The clusters peak at a distance of about 3.0 Å from the nitrogen atoms. 7% of these water molecules are shared between NH1 and NH2, and only 3% are shared between the Nε and NH1 atoms. The distribution around the Lys side chain is much broader and is qualitatively similar to the one shown for Ser in Fig. 23.5.3.1(*c*), with no particular orientational preferences, mainly due to the freely rotating nature of the Cε—Nζ bond.

His and Trp are the two residues that contain ring nitrogen atoms, which comprise the main site of interaction with water molecules for these side chains. The distributions of water molecules within 3.5 Å of these residues are shown in Figs. 23.5.3.1(*h*) and (*i*). The clustering around His shows a peak at 2.7 Å and a larger peak at 3.1 Å. The closer peak corresponds to interactions with deprotonated nitrogen (Nδ), where the lone pair of electrons renders the deprotonated nitrogen more negatively charged than the corresponding protonated nitrogen (Nε) and, therefore, the deprotonated nitrogen pulls the water molecule closer. The peak at 3.1 Å is due to water interactions with the protonated nitrogen (Nε) of His. There is a strong preference for the water molecules to lie in the plane of the ring. Relatively few water molecules exist within 3.5 Å of Trp. They mostly cluster around the Nε nitrogen at varying distances. The number of water molecules interacting with His and Trp within 5.0 Å of the ring increases greatly and peaks at a distance of about 4 Å, as discussed below for hydrophobic residues in general (Walshaw & Goodfellow, 1993).

Table 23.5.3.1

Specific hydrophilicity values for protein atoms

Atom type	Hydrations per occurrence†
Neutral oxygen	0.53
Negative oxygen	0.51
Positive nitrogen	0.44
Neutral nitrogen	0.35
Carbon, sulfur	0.08

† The average number of hydrations per occurrence was calculated over all atoms within each group.

Overall, there seem to be weaker geometric constraints on oxygen acceptors compared to nitrogen donors. Furthermore, the water interaction with oxygen atoms peaks at a distance of about 2.8 Å, while the interactions with protonated nitrogen atoms occur at a somewhat longer distance of about 3.1 Å. This is possibly due to the larger van der Waals radius of nitrogen (1.8 Å) *versus* that of oxygen (1.7 Å) (Thanki *et al.*, 1988). A subsequent study of hydration around polar residues is based on seven proteins solved to better than 1.4 Å resolution (Roe & Teeter, 1993). The authors used cluster analysis to derive a predictive algorithm to locate water sites around polar side chains on protein surfaces, given the atomic coordinates of the protein alone. These more precise results confirm the general conclusions outlined above. The authors find that the water–oxygen distance is less than that of water–nitrogen by 0.07 Å and suggest the difference to be due to a van der Waals radius of 1.5 Å for nitrogen and 1.4 Å for oxygen (Roe & Teeter, 1993). Although the two groups cite different atomic radii for nitrogen and oxygen, this does not have an effect on the statistical analysis of the data. Roe & Teeter (1993) also find that the clusters associated with nitrogen atoms are approximately two times denser than those around oxygen atoms.

The analysis of the local water structure around the apolar side chains Ala, Val, Leu, Ile and Phe was extended to a distance 5.0 Å from the atom of interest, since these residues show only a few water molecules within the 3.5 Å cutoff used to analyse interactions with polar residues. The most noticeable observations from the analysis of apolar side chains are the water peak at a distance of 4 Å from the carbon atoms of interest and the presence of a polar protein atom within a hydrogen-bonding distance for 75% of these water molecules (Walshaw & Goodfellow, 1993). Phe prefers in-plane interactions and has peaks corresponding to the direction of the Cε1, Cε2, Cδ1 and Cδ2 atoms from the centre of the ring. Otherwise, any clustering observed for water molecules near apolar side chains is due to interactions with polar protein atoms and, consequently, is modulated by secondary structure.

A study of protein hydration based on atomic and residue hydrophilicity presents general results consistent with those discussed above, but also adds information that can be correlated with various experimentally and computationally derived hydrophilicity–hydrophobicity scales (Kuhn *et al.*, 1995). The authors used 10 837 water molecules found in 56 high-resolution protein crystal structures to obtain the average number of hydrations per occurrence over each amino-acid type and specific atom types. The hydration of the various amino-acid residues has already been discussed above. The atomic hydrophilicity values calculated for the different protein-atom types are of interest.

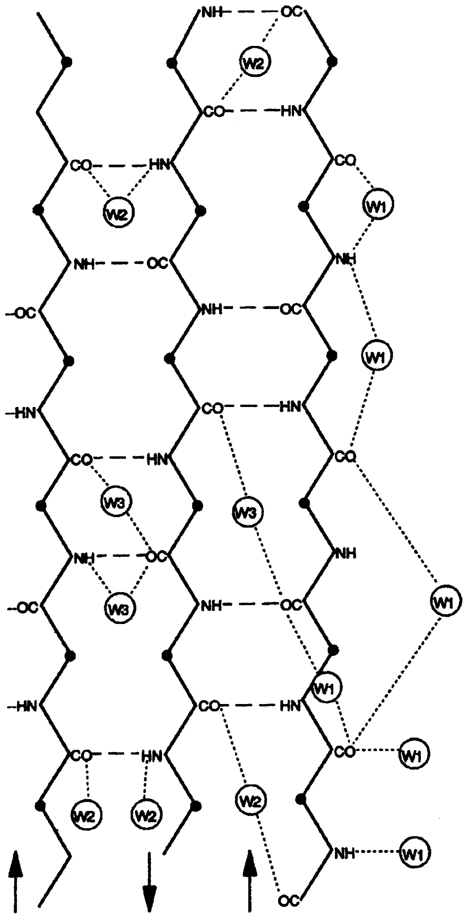

Figure 23.5.3.3
Diagram of edge (W1), end (W2) and middle (W3) categories of interactions of water molecules with main-chain atoms in antiparallel β-sheets. Reprinted with permission from Thanki *et al.* (1991). Copyright (1991) Academic Press.

Fig. 23.5.3.2 and Table 23.5.3.1 show that, regardless of where these atoms are found, neutral oxygen atoms exhibit the greatest hydration level per occurrence, closely followed by negatively charged oxygen atoms, which in turn are followed by positively charged nitrogens and neutral nitrogens, in that order. Carbon and sulfur atoms are indistinguishable in terms of hydration per occurrence and are grouped together as the least hydrated atoms (Kuhn *et al.*, 1995).

23.5.3.2. The effect of secondary structure on protein–water interactions

The main effect of secondary structure is on the hydration of main-chain carbonyl oxygens and amido nitrogen atoms. The clustering of water molecules around the small aliphatic apolar side chains (Walshaw & Goodfellow, 1993) and the Ser and Thr side chains (Thanki *et al.*, 1990) were also found to be guided by interactions with main-chain atoms belonging to a specific secondary structure. Other side chains are too large to have their hydration significantly affected by secondary structure. The broad solvent distribution around Ser and Thr side-chain hydroxyl oxygen atoms results from the combination of complex, but distinct, patterns that emerge when hydration around these side chains is examined separately in α-helices and β-sheets. Preferential hydrogen-bonding positions around Ser and Thr residues result from water molecules bridging between the hydroxyl group and another polar protein atom within the α-helix or β-sheet. These positions are dependent both on the χ_1 torsion angle and the type of secondary structure within which these residues are found (Thanki *et al.*, 1990).

The analysis of main-chain hydration focused separately on hydration of β-sheets, α-helices and turns (Thanki *et al.*, 1991). In general, more water molecules were found to interact with carbonyl oxygens than with amide groups, due primarily to the fact that carbonyl oxygen atoms can accept two hydrogen bonds, whereas amido groups can donate a single one. Thus, free carbonyl oxygen atoms have the potential to interact with two water molecules, whereas those already involved in a secondary-structure interaction with the protein still have a lone pair of electrons that can accept a hydrogen bond from a water molecule. Of the free carbonyl oxygen atoms within secondary-structure elements, 45% of those in α-helices and 68% of those in β-sheets interact with water molecules. Of those that are involved in secondary-structure interactions within the protein, 21% of those in α-helices and 17% of those in β-sheets also interact with solvent. The free amide groups are well hydrated, with 38% of those in α-helices and 54% of those in β-sheets interacting with water molecules. However, virtually none (2% in helices and 6% in sheets) of the amides already involved in secondary-structure hydrogen bonding also interact with a water molecule.

Three types of interactions were observed for water molecules in the context of β-sheets (Fig. 23.5.3.3). Most (68%) of these interactions are with the edge of the β-sheet, in an extension of the secondary structure. The second most prominent type of interaction, comprising 23% of the total, is at the ends of the β-strands with either free amido or carboxyl groups. Finally, only 10% of the water molecules are found to bridge between two strands in the middle of the β-sheet.

Interactions of water molecules with α-helices are also found in three distinct positions relative to the secondary structure (Fig. 23.5.3.4): at the carbonyl terminus of the helix, at the amido terminal end and in the middle. Of those interacting at the carbonyl terminus, 48% interact with the carbonyl oxygen alone, 11% also interact with a nearby main-chain atom and 41% are involved in a water-mediated C cap, bridging a small polar side chain (Ser, Thr, Asp, or Asn) to a free carbonyl group at the end of the helix. Of water molecules interacting at the amido terminus of the helix, 25% interact with free amido groups alone, 45% bridge to local main-chain atoms and many of the remaining mediate in N-cap interactions with small polar side chains such as Ser and Asp.

In general, turns have a high exposure to solvent and therefore are found to be well hydrated. The pattern of hydration varies both with the type of turn and the location of the atoms within the turn. Not surprisingly, there are about twice as many hydrogen bonds to carbonyl groups as there are to amide groups in turns. Although the majority of the water interactions with turns are to single carbonyl oxygen or amido nitrogen atoms, bridging water molecules do appear, especially within more open turns. They occur in a variety of different patterns, bridging between two main-chain atoms in the turn or between a main chain and a small polar side chain.

Clearly, water molecules play a functional role in maintaining the integrity of the secondary-structure elements of proteins. They are often seen to extend α-helices or β-sheets, serving as an interface between these secondary-structure elements and the bulk solvent. Water molecules are also found to mediate the interaction between two protein atoms within a given secondary structure that may be too far from each other to interact directly. This may be of great importance in turns, particularly the more open ones where the protein atoms are not in ideal positions to form a tight two-residue β-turn.

23.5.3.3. The effect of tertiary structure on protein–water interactions

At the tertiary level, there is an interdependence between protein surface shape and the extent of water binding (Kuhn *et al.*, 1992). Kuhn *et al.* (1992) studied the binding locations of 10 837 water molecules found in 56 high-resolution crystal structures using fractal atomic density and surface-accessibility algorithms. They found strong correlations between the positions of water molecules and protein surface shape and amino-acid residue type. A probe sphere with the radius of a water molecule revealed that, in general, protein surfaces exhibit convex groove areas and concave contact surfaces. Although grooves account for approximately one quarter of a given protein surface, they bind half the water molecules. Furthermore, only within grooves was hydration found to be dependent on residue type, with charged and polar residues as well as main-chain nitrogen and oxygen atoms exhibiting a greater degree of hydration than the non-polar residues. Outside the grooves, there was a low residue-independent hydration level, with no distinction between main-chain and side-chain atoms (Kuhn *et al.*, 1992). Levitt & Park (1993) discuss the paradox between the experimental observation that water molecules are crystallographically observed primarily in crevices (Kuhn *et al.*, 1992) and the results from theoretical calculations that argue that surface tension should make crevice waters bind less strongly (Nicholls *et al.*, 1991).

While the majority of the crystallographically observed water molecules appear on the outer protein surface, the internal protein packing is not perfect, so that the three-dimensional fold usually results in a number of internal cavities that can accommodate buried water molecules. The first analysis of such cavities was based on a small set of 12 proteins for which the authors characterized such sites by their size and area, as well as by whether or not they were occupied by crystallographically observed water molecules (Rashin *et al.*, 1986). More recently, two methodologically distinct studies of intramolecular cavities used much larger databases to provide extensive and mutually consistent conclusions regarding the properties of these sites (Hubbard *et al.*, 1994; Williams *et al.*, 1994). Hubbard *et al.* (1994) analysed 121 protein chains, with no two possessing a pairwise identity greater than 40%. This study is based on a systematic method of determining the shape as well as the size of the internal cavities and categorizes each cavity as either 'solvated' (with crystallographically visible water molecules) or 'empty' (with no crystallographically visible water molecules), noting the amino-acid-residue preferences in each type. Hydrogen-bonding patterns were also noted within the solvated sites. The second study (Williams *et al.*, 1994) selected 75 non-homologous monomeric proteins, solved at 2.5 Å resolution or better. Although the authors noted the general shape, size and location of cavities, the focus of this study was on the buried water molecules and the hydrogen-bonding patterns that they form within these sites.

In general, larger proteins are able to tolerate larger cavity sizes than small proteins, and nearly all proteins with more than 100 amino-acid residues are found to have at least one cavity. These cavities are found in the protein interior at a variety of distances from the surface and reflect the difficulty of perfect packing within the core. In the database of 121 proteins (Hubbard *et al.*, 1994), 265 cavities were found to be 'solvated' and 383 were 'empty'. The solvated cavities tend to be nearer to the protein surface than the empty cavities. Nearly 60% of the solvated cavities are occupied by a single water molecule and are of spherical shape. About 20% accommodate two water molecules, and 20% more are found to contain larger clusters (Williams *et al.*, 1994). These tend to have an elongated cigar shape. The cavity volume can be as large as 216 Å^3 (an elastase cavity containing seven water molecules). The solvated cavities tend to be larger than the empty ones, with average volumes of 39.4 and 20.7 Å^3, respectively (Hubbard *et al.*, 1994). The mean volume per water molecule in a cavity is 27 Å^3, as compared to 30 Å^3 in bulk water, suggesting that a water molecule is not favourably squeezed into a volume comparable to its own (11.5 Å^3), but rather occupies similar volumes upon transfer from the bulk into the protein interior.

Solvated cavities differ from empty ones not only in location and size within the protein, but also in the constitution of the amino-acid residues lining the cavity and the secondary-structure elements that are nearby. While 50% of the total cavity molecular surface is provided by polar atoms in solvated cavities, this fraction reflects only 16% of the empty cavity surface. Polarity, not size, is the predominant factor in determining the solvation state of a cavity. Interestingly, solvated cavities have more surface area provided by coil residues than the empty cavities, often found to be lined by residues in secondary structure (Hubbard *et al.*, 1994).

There is on average one buried water molecule per 27 amino-acid residues, although there is great variation

between individual proteins. These water molecules most commonly form at least three hydrogen bonds with protein atoms or other buried water molecules. Only 18% of buried water molecules make two or fewer polar contacts. Of all of the hydrogen bonds made by buried water molecules, 53% are to protein backbone atoms, 30% to protein side-chain atoms, 17% to other buried water molecules, and 3% make no visible polar contacts at all (Williams *et al.*, 1994).

The appearance of cavities in the protein core is a consequence of the optimal packing of the protein polypeptide chain as it folds into the native, functional state. Where these cavities expose polar atoms to the hydrophobic protein core, one or more buried water molecules effectively become part of the structure, serving to maintain the protein integrity by fulfilling the hydrogen-bonding potential of atoms which are more favourably solvated.

23.5.3.4. Water mediation of protein–ligand interactions

A series of three papers presents the results of an analysis of water molecules mediating protein–ligand interactions in 19 crystal structures solved to better than 2.0 Å resolution and refined to an *R* factor of at least 23% (Poormina & Dean, 1995*a*,*b*,*c*). The studies focus on hydrogen-bonding features of water molecules bridging protein–ligand complexes (Poormina & Dean, 1995*b*), on the surface shape of the protein and ligand molecules at the water-binding sites (Poormina & Dean, 1995*c*), and on the structural and functional importance of water molecules conserved at the binding sites in five sets of evolutionarily related proteins (Poormina & Dean, 1995*a*). This study was largely motivated by an attempt to distinguish between properties of water-binding sites where water molecules are displaced by ligands and those where water molecules must be considered as part of the protein surface. This type of understanding has direct implications for drug and ligand design.

In general, there is a strong correlation between the number of water molecules found to bridge any given protein–ligand complex and the number of hydrophilic groups associated with the ligand. Within this context and in agreement with the conclusions of Kuhn *et al.* (1992), the authors found that the protein shape is important in determining the location of water-binding sites at the protein–ligand interface. Fig. 23.5.3.5 illustrates the different types of grooves observed in this study. Figs. 23.5.3.5(*a*) and (*b*) represent binding of bridging water molecules in deep grooves on the protein or on the ligand, respectively. The most common situation is illustrated in Fig. 23.5.3.5(*a*), with that in Fig. 23.5.3.5(*b*) occurring very rarely. Fig. 23.5.3.5(*c*) shows the situation where water molecules are found to interact with the ligand alone or at the periphery of the protein–ligand interface. Finally, Fig. 23.5.3.5(*d*) illustrates the situation where clusters of water molecules occupy elongated grooves, mediating the protein–ligand interaction. A striking example of this is given by the complex between chloramphenicol acetyl transferase and chloramphenicol, where two clusters of water molecules are found to form a layer between the enzyme and the ligand (Poormina & Dean, 1995*c*).

For the purposes of analysis, the authors distinguish between water molecules that interact with both protein and ligand, forming a bridge between the two, and water molecules that interact with either the protein or the ligand, but not with both. There is also a group of water molecules that interact with neither protein nor ligand, but are thought to contribute to the stability of the network of water molecules at the protein–ligand interface.

Of the 58 water molecules found to bridge between protein and ligand, 38 (nearly 80%) make three or more hydrogen bonds and satisfy tetrahedral geometry. Furthermore, they bind in deep grooves, generally interacting more strongly with the protein (Fig. 23.5.3.5*a*). The *B* factors of these bridging water molecules are comparable to those of the protein atoms with which they interact. They can, in effect, be considered an integral part of the protein structure and binding site. Many of these bridging water molecules are conserved throughout homologous proteins, even when different ligands are considered, and are clearly structurally significant in maintaining the properties of the protein binding sites.

Water molecules found to bind in shallow grooves do so either at the ligand surface or at the periphery of the protein–ligand interface. For many of these water molecules, the surface areas of the protein and the ligand exposed to the same water molecule are nearly equal. Water molecules binding in shallow grooves are found to have zero to two polar contacts with the protein and are not particularly well conserved within families of homologous proteins.

In general, the authors conclude that water molecules that are to be considered as part of the protein binding site during the design of a new ligand are those that bind in deep grooves, making multiple hydrogen bonds to protein atoms. These water molecules tend to be conserved through families of homologous proteins. The amino-acid residues that interact with deep-groove water molecules tend to be more conserved compared with other residues interacting with the ligand. Conversely, the binding of water in shallow grooves does not seem to be influenced by any special general feature of the protein or ligand surface, and it would be difficult to select water molecules *a priori* for inclusion as part of the protein structure during the process of ligand design.

23.5.4. Water structure in groups of well studied proteins

The analysis of general features of protein–water interactions derived from large databases provides an important context for the study of solvent structure in individual proteins. The number of crystallographically visible water molecules in any one X-ray structure depends on the resolution of the data, the degree of refinement of the model, the criteria used for placement of the less well defined water molecules, and on the experience of the crystallographer. Therefore, to differentiate between water molecules that have functional roles and those that associate randomly with the protein, it is desirable to determine commonalities between several independently solved structures of the protein of interest. There are different types of functional roles that can be determined at several levels. At the global level, one can find a small number of water molecules that are essential for the structural architecture common to a given family of homologous proteins. There are also those water molecules that are structurally important for a specific protein, being present in all independently solved structures of that protein, regardless of the crystal form in which the water molecule was determined or of its interactions with ligands. Water molecules that consistently appear in crystal structures of the protein solved in a specific space group but in no others may be important for crystal packing, but not to the integrity of the protein itself. Finally, a given water molecule may be essential for mediating in a protein–ligand complex, but never appear in the native protein. At this level, all of the independently solved structures of the complex would have the water molecule present. In the examples that follow, comparative analysis between carefully selected groups of structures reveals conserved water molecules at all of these different levels and shows how they carry out particular functional roles in specific examples.

23.5.4.1. Crystal structures of homologous proteins

There are two families of homologous proteins for which extensive solvent-structure comparisons have revealed water molecules important in maintaining structural features common to all members of the family. In the first study presented here, 35 crystal structures of eight members of the serine protease family were analysed (Sreenivasan & Axelsen, 1992), while the second study comprises a similar analysis of 11 independently solved structures of six members of the legume lectin family (Loris *et al.*, 1994).

23.5.4.1.1. Serine proteases of the trypsin family

The serine proteases have an especially large number of buried water molecules. Using a probe sphere of radius 1.4 Å, an iterative procedure was used to delete all accessible surface waters for each structure of chymotrypsin, chymotrypsinogen, trypsin, trypsinogen, elastase, kallikrein, rat tonin and rat mast cell protease. A total of 58 non-equivalent sites containing buried water molecules were found in the 35 crystal structures included in the study. Of these, 16 sites were common to all of the structures, with five additional sites common to proteins sharing the primary specificity of trypsin. A protein environment was defined for each of these 21 water sites to consist of the set of non-hydrogen protein atoms within 5 Å of the water oxygen atom. There are an average of 29 protein atoms per buried water molecule. Of these, 87% consist of main-chain atoms or conserved amino-acid side-chain atoms. The highly conserved nature of the amino-acid residues lining these water-binding sites suggests that the corresponding water molecules are important components of the protein tertiary structure and are likely to be present in all of the members of the trypsin family of serine proteases (Sreenivasan & Axelsen, 1992). Proteins in this family have two β-sheet domains, with the active site in the cleft between these domains. A large portion of the conserved buried water molecules occur in this cleft, mediating the interaction between the domains (Fig. 23.5.4.1). Conserved buried water molecules in other areas are found to bridge secondary-structure elements. These water molecules have been analysed extensively for elastase and are discussed in more detail below (Mattos, 2002).

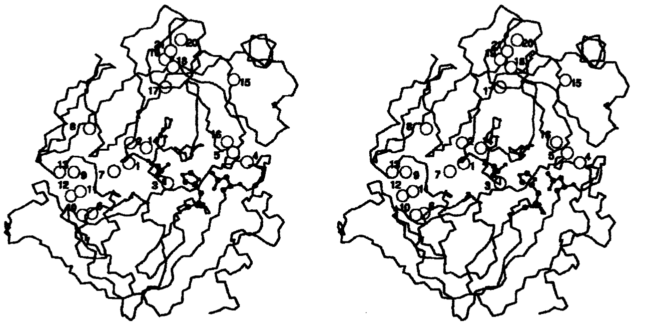

Figure 23.5.4.1
Stereoview of the set of 21 highly conserved buried waters in eukaryotic serine proteases. The trypsin backbone is represented as a stick drawing, with the catalytic triad at the centre (filled circles). Water molecules are represented as open circles. Reprinted with permission from Sreenivasan & Axelsen (1992). Copyright (1992) American Chemical Society.

23.5.4.1.2. Legume lectin family

Whereas the study on serine proteases described above focused on the buried water molecules, the study on the legume lectin family included all of the conserved water molecules in the first hydration sphere. A total of 11 crystal structures were superimposed, many of them containing two independently refined monomers, making a total of 21 crystallographically independent monomers (Loris *et al.*, 1994). The six different proteins in the family (lentil lectin, pea lectin, *Lythyrus* lectin, *Griffonia* isolectin IV, *Erythrina* lectin and concanavalin A) have sequence identities ranging from 100% to 40%. Water molecules in two superimposed crystal structures were considered to occupy the same site if they were within a predefined distance of 1 Å from each other. Seven water sites were found to be conserved in all of the family members included in the study. Four of these interact with the manganese and calcium ions, and one is in the ligand-binding site. The other two stabilize secondary structures: a β-hairpin turn and a β-bulge. In all cases, the protein composition of the site was strictly conserved. A larger number of water molecules are conserved within groups of closely related members of the family. The majority of these sites are found in the interface between the two monomers that come together to form a continuous 12-stranded β-pleated sheet and around the metal and monosaccharide binding regions (Fig. 23.5.4.2). Three crystal forms of lentil lectin were available for the study, and it was observed that of the 33 water molecules conserved between the corresponding three structures, none are involved in crystal contacts.

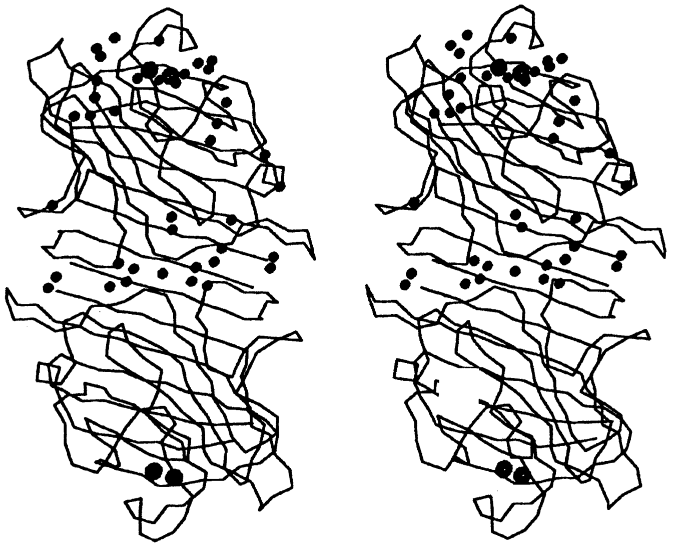

Figure 23.5.4.2
View of the 33 conserved hydration sites in the lentil lectin crystal structures superimposed on the backbone of the lentil lectin dimer. If one could generalize from the two studies described above, the conclusion would be that the water molecules strictly conserved across families of homologous proteins are found either at the binding site, at the interface between domains, or bridging secondary-structure elements which would otherwise not be part of the well defined protein architecture. Furthermore, it is clear that evolutionary pressure exists to maintain the composition of the amino-acid residues with which these crucial water molecules interact at their respective protein binding sites. A more recent study of conserved water molecules in a large family of microbial ribonucleases confirms the conclusions obtained in the two studies presented here (Loris *et al.*, 1999).

23.5.4.2. *Multiple crystal structures of the same protein*

Although not many studies have focused on the conserved water molecules across families of homologous proteins, there is currently a considerable amount of information on solvent structure based on groups of independently solved crystal structures of a specific protein. The comparison of multiple crystal structures is important to distinguish between the different roles played by water molecules on protein surfaces and to obtain a more complete picture of the first hydration sphere. In any one crystal structure of a given protein, it is extremely likely that the water molecules crucial to the structure or function of the protein will be seen in the electron-density map. However, the water molecules more loosely associated with the protein surface appear fortuitously in one or few structures, so that with every new structure one finds a series of water molecules not previously observed. A clear example of this is provided by a collection of eleven elastase structures solved in different organic solvents, where of a total of 1661 water molecules there are 178 molecules that are unique to one of the structures (Mattos & Ringe, 1996; Mattos, 2002; Mattos *et al.*, 2006).

23.5.4.2.1. *Elastase*

The crystal structure of porcine pancreatic elastase was solved in a variety of organic solvents, with the primary goal of mapping binding sites on the protein that could accommodate molecules representative of functional groups likely to be found in larger ligands (Ringe, 1995; Mattos & Ringe, 1996; Mattos *et al.*, 2006). Crystals of elastase cross-linked with glutaraldehyde were transferred to the following solutions: 100% acetonitrile, 95% acetone, 55% dimethylformamide, 80% ethanol, 40% trifluoroethanol, 80% isopropanol and 80% 5-hexene-1,2-diol (Mattos *et al.*, 2006; Mattos & Ringe, 1996). In general, the crystals did not diffract in most neat organic solvents. However, in the acetonitrile case, where they did, the result was striking. In the structure of elastase solved in >99% acetonitrile, there were 126 water molecules visible in the electron-density maps, indicating that a good portion of the first hydration shell of the protein was still present. In contrast, only nine molecules of acetonitrile were clearly identified in the electron-density maps (Allen *et al.*, 1996). This is a powerful assertion of the evolutionary specificity of water molecules for protein surfaces. Fig. 23.5.4.3 shows the clear contrast between the elongated electron density of an acetonitrile molecule and the spherical electron density of a water molecule.

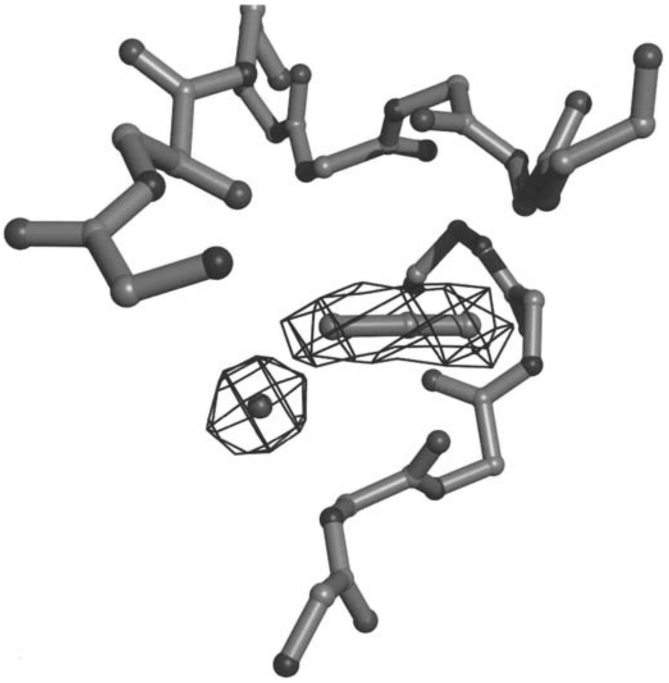

Figure 23.5.4.3
A $2F_o - F_c$ electron-density map contoured at the 1.2σ level shows a distinct ellipsoidal density for acetonitrile 707 and a spherical density for a nearby water molecule. The protein backbone of the binding pocket is represented with nitrogen atoms shown in dark grey, oxygen atoms in medium grey and carbons in a lighter grey. *MOLSCRIPT* (Kraulis, 1991) was used in the preparation of this figure. Reprinted with permission from Allen *et al.* (1996). Copyright (1996) American Chemical Society.

A similar result was obtained for all of the elastase structures solved in the mixtures of organic solvent and water mentioned above. A total of 11 structures were analysed, each containing 126–177 water molecules. The structures are listed in Table 23.5.4.1, together with the resolution of the data collected, the number of water molecules present and the number of organic solvent molecules observed in each case. The Cα superposition of the protein atoms in the 11 structures yielded a total of 1661 individual water molecules, occupying 426 unique water-binding sites on the elastase surface. Given that elastase has a total of 240 amino-acid residues, this represents a significant portion of the first hydration shell of the protein. This group of elastase structures served as a powerful source of information, leading to a

Table 23.5.4.1
Multiple-solvent crystal structures of elastase

Structure	Resolution (Å)	No. of water molecules	No. of organic solvent molecules
Cross-linked	1.9	165	0
Acetonitrile	2.2	126	9
Acetone	2.0	126	6
Dimethylformamide	2.0	153	6

Trifluoroethanol (1)	1.9	175	4
Trifluoroethanol (2)	1.85	177	3
Isopropanol	2.2	160	4
Benzene	1.9	162	4
Cyclohexane	1.95	135	7
5-Hexene-1,2-diol	2.2	147	5

classification of water types according to their interaction with the protein and an analysis of the specificity for water within each of the types determined (Mattos, 2002; Mattos *et al.*, 2006).

All of the 1661 water molecules were renumbered according to the site on the protein where they were found. Any two water molecules within 1 Å of a water molecule in the cross-linked elastase structure solved in distilled water (used as the reference structure) have a common number. Thirty-nine of the 426 water-binding sites were occupied in every one of the 11 structures and were considered structurally conserved. Among these are the 16 buried water-binding sites thought to be conserved among all serine proteases (Sreenivasan & Axelsen, 1992). The 26 remaining conserved water molecules are specific to elastase and are not necessarily buried. These water molecules in general tend to have low B factors, but a few have B factors in the 30–35 Å^2 range and one set of conserved water molecules have B factors in the 40 Å^2 range.

The classification of the water sites as buried, channel, crystal contact or surface was based on the number of hydrogen-bonding interactions that a water molecule at the site could make to the protein and involved no surface-accessibility calculations (Mattos, 2002). Water molecules were classified as buried if they made at least three good hydrogen-bonding interactions with protein main-chain atoms. A total of 23 buried water sites were identified in this manner, including 13 of the sites classified as buried by Sreenivasan & Axelsen (1992). One of the 16 serine protease conserved water-molecule sites is replaced by a His side chain in elastase (Sreenivasan & Axelsen, 1992). The remaining two serine protease conserved water sites were classified as channel based on the criteria used in the present study (see below). Interestingly, with the exception of these two channel water molecules, all of the buried sites found to be conserved in serine proteases are strictly conserved in all of the 11 structures in Table 23.5.4.1. The two channel water molecules are found in the aqueous structures of elastase, but are virtually absent in elastase transferred to organic solvents.

The water molecules occupying the 23 buried water sites identified in this study are tightly clustered when the protein Cα atoms are superimposed by least squares, and the interactions with the protein are conserved from structure to structure. Fig. 23.5.4.4 shows the positions of the buried water-binding sites in elastase. In general, they are found in the cleft between the two domains, in bridging elements of the secondary structure and at the base of water channels. This observation is consistent with the current understanding of the functional roles played by structurally conserved water molecules as discussed above and in the following sections.

The 29 water-binding sites classified as channel contain water molecules that make hydrogen bonds with at least two other water molecules within a protein groove. The analysis of a high-resolution crystal structure of elastase (1.65 Å) revealed seven channels with a total of 32 water-binding sites (Meyer *et al.*, 1988). All of these channels were also identified in the analysis of the 11 structures in Table 23.5.4.1. In addition, two other channels were observed. The locations of the nine elastase channels identified by the new criteria are shown in Fig. 23.5.4.5. Channels are often found in areas associated with buried water molecules, namely, at the crevice between the two domains and sandwiched between secondary-structure elements, where they lead from the surface of the protein to a buried water molecule. Fig. 23.5.4.5 also shows that the Cα superposition of the protein structures leads to a spread of water molecules within the channels. In any given structure, only two or three water molecules may be present, but the precise location and interaction with protein atoms vary so that when taken together the collection of structures gives a sense of flow inside the channels.

Of the remaining 374 water-molecule sites present within the 11 elastase structures included in this study, 56 were classified as crystal-contact sites and 318 as surface sites. Crystal-contact sites were considered to be occupied by water molecules that are within 4.0 Å of a symmetry-related protein molecule in the crystal. Fig. 23.5.4.6 shows the position of all the water molecules found to occupy these sites. The relatively large number of crystal-contact water-binding sites is a result of the somewhat broad criterion used to select them. Many of these sites are not

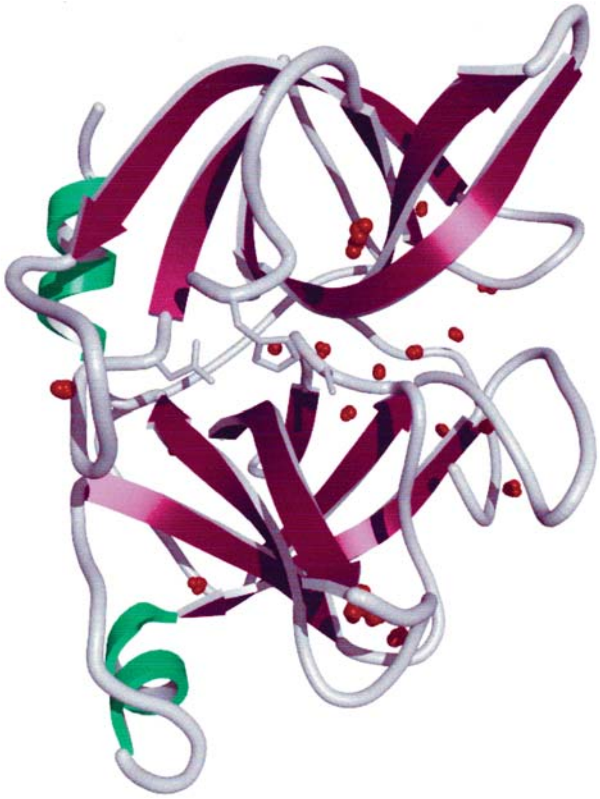

Figure 23.5.4.4
Crystal structure of porcine pancreatic elastase represented as a ribbon diagram using *MOLSCRIPT* (Kraulis, 1991). The two α-helices are shown in green, the β-sheets are in purple and the coils are in grey. Elastase contains 240 amino-acid residues, and is composed of two β-barrel domains. The catalytic triad (Asp108, His60 and Ser203) is shown explicitly. The buried crystallographic water molecules found in 11 superimposed elastase structures solved in a variety of solvents are shown in red.

within hydrogen-bonding distance from the nearby protein molecule, and most are not well conserved from structure to structure. Only eight of the 56 sites are occupied in the majority of the structures, and four of these make good multiple hydrogen bonds with two symmetry-related protein molecules in the crystal. These four water molecules seem to be structurally significant in the formation of the crystal contacts.

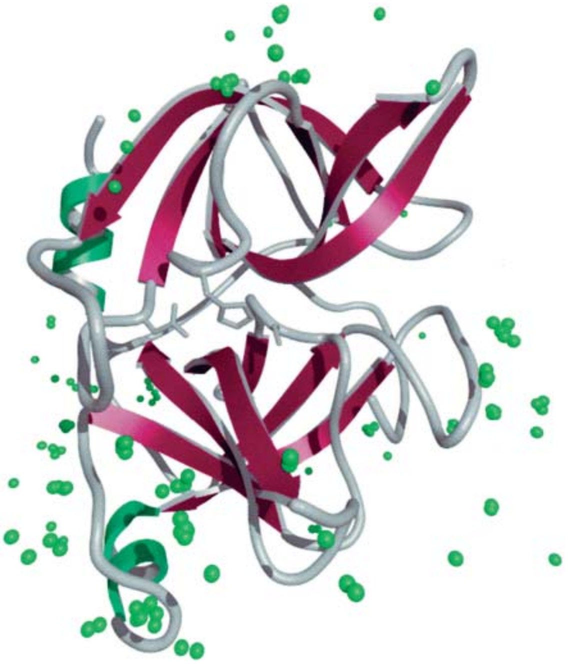

Figure 23.5.4.6
Elastase structure represented as in Fig. 23.5.4.4. The crystallographic water molecules involved in crystal contacts in 11 superimposed elastase structures solved in a variety of solvents are shown in green.

Surface water molecules were taken to be those that interact with side-chain protein atoms on the surface or make no more than two hydrogen bonds with backbone atoms. When the 11 structures are superimposed, the surface water molecules occupying a given site are not tightly clustered. Furthermore, there is flexibility in the interactions between these water molecules and the nearby protein atoms. For example, it is often the case that all water molecules within a surface site make two or three hydrogen bonds to protein atoms, but only one of them is conserved in all of the structures where the water molecule is present at the site. Fig. 23.5.4.7 illustrates the position of all of the surface water-binding sites. Although over half of these sites are occupied in at least two of the 11 structures, a good proportion of them (178) are found in only one of the structures considered.

While crystal-contact and surface water sites were classified separately, it is important to point out that, with the exception of the four crystal-contact water-binding sites mentioned above, the crystal-contact sites exhibit very much the same traits as the surface water sites. The difference is that in the latter case, the 'surface' is provided by a single protein molecule, while in the former the interaction between two symmetry-related protein molecules constitutes the surface with which the water molecules interact.

Of the 318 surface water molecules, 21 are in the active site. The active-site water molecules were selected to be those within 4 Å of any atom belonging to either the trifluoroacetyl-Lys-Phe-*p*-isopropylanilide (Mattos *et al.*, 1994) or the trifluoroacetyl-Lys-Pro-*p*-trifluoromethylanilide (Mattos *et al.*, 1995) inhibitors in the structures of their complexes with elastase. These inhibitors span a large area of the active site, including an exosite not occupied

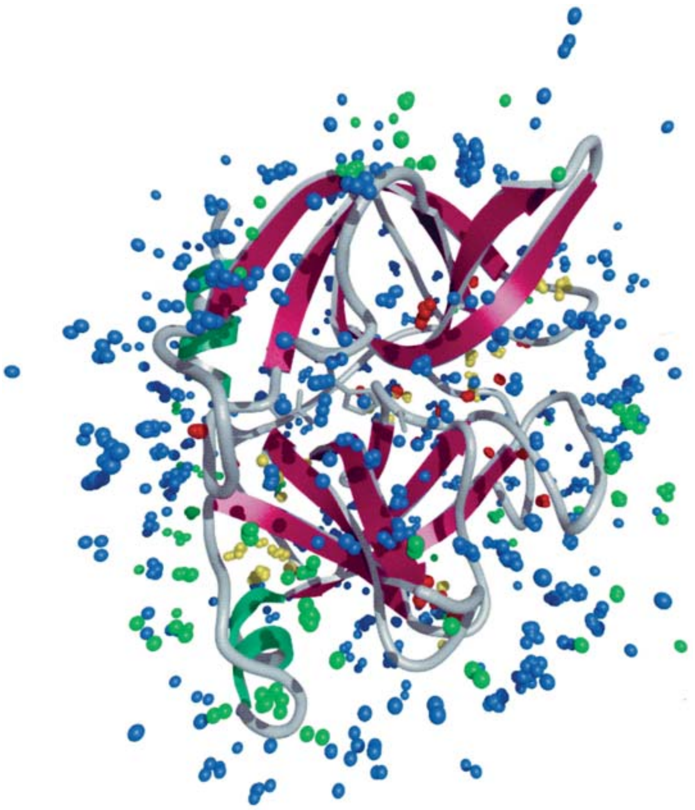

Figure 23.5.4.8
Elastase structure represented as in Fig. 23.5.4.4. The 1661 water molecules found in 11 superimposed elastase structures of elastase are colour-coded as in Figs. 23.5.4.4–23.5.4.7.

by substrate analogue inhibitors (Mattos *et al.*, 1994, 1995). The water-binding sites in the active site are not very well conserved, with most sites represented in only two to four of the 11 structures. When all of the structures are superimposed, there is at least one water molecule in each of the subsites in the elastase active site. These water molecules are displaced either by inhibitors or by organic solvent molecules in the various structures. It is not surprising that in elastase, a protein with relatively broad substrate specificity, the active site in the uncomplexed native protein is populated by many displaceable surface water molecules. With the exception of a water molecule present in the oxyanion hole, these water molecules tend to make a single hydrogen bond with the protein. This hydrogen-bonding interaction is not generally conserved between different structures where a given site is occupied in multiple structures. The displacement of these water molecules upon ligand binding is entropically favourable, as they are released into bulk solvent, without too much enthalpic cost. This relatively small enthalpic cost can be compensated by the protein–ligand interactions.

Fig. 23.5.4.8 shows all of the 1661 water molecules colour-coded by the various classifications described above. Clearly, the entire surface of the protein is well hydrated. Notice how the yellow channel waters are often followed by a red buried water molecule. In addition, there is often no obvious spatial distinction between molecules categorized as crystal contacts (green) and those categorized as surface (blue).

23.5.4.2.2. *T4 lysozyme*

Over 150 mutants of T4 lysozyme have been studied to date, and, for the majority of these, the crystal structures are available. Although most of the mutant structures crystallize isomorphously to the wild type, many of them provide a view of the molecule in different crystal environments. This collection of structures leads to the comparative analysis of the solvent positions in ten different crystal forms of T4 lysozyme, providing a clear picture of the effect of crystal contacts on the hydration sphere of a protein viewed by X-ray crystallography (Zhang & Matthews, 1994). The resolution and degree of refinement of the structures involved varied significantly, from 2.6 to 1.7 Å resolution, and the number of water molecules included per protein molecule ranged from 38 to 160. Nevertheless, this study revealed important features. A striking observation is that 95% of the solvent-exposed residues on T4 lysozyme were involved in at least one crystal contact in one or another of the crystal forms studied, showing that any part of the protein surface can be involved in crystal contacts. A corollary to this finding is that any of the surface water molecules can be displaced or involved in bridging protein–protein contacts in the crystal.

Of the 1675 individual water molecules observed in the 18 independently refined T4 lysozyme molecules included (Fig. 23.5.4.9), the ones that were within a sphere of radius 1.2 Å were considered to occupy the same site on the protein. As in the case of elastase described above, all of the water molecules observed upon superposition of the 18 T4 lysozyme structures represent a large portion of the first hydration shell. This reinforces the concept that multiple structures of a protein of interest provide a more complete picture of the protein hydration than possible with a single structure. There are four buried water sites that are occupied in at least 15 out of the 18 structures and are independent of crystal contacts. Two of these buried sites are at the hinge-bending region between the two helical domains and appear to play a functional role in the opening and closing of the

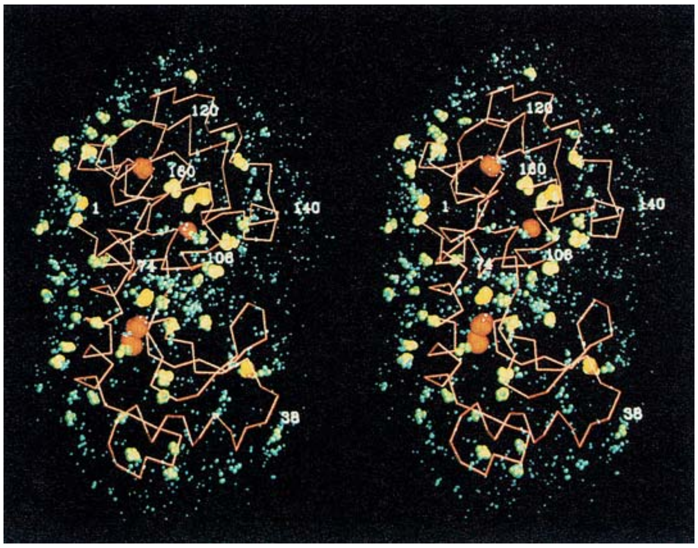

Figure 23.5.4.9
Distribution of solvent-binding sites in 18 mutant T4 lysozymes from ten refined crystal structures. The lysozyme structures were compared to identify common sites of hydration. A total of 1675 solvent molecules were included in the comparison. Each solvent molecule is represented by a coloured sphere. The size of the sphere is proportional to the number of lysozyme structures in which solvent was observed at the same site (*i.e.* within 1.2 Å). In addition, the colour of the solvent changes from blue for the least-conserved sites to red for the most-conserved ones [*e.g.* the red spheres indicate that solvent is observed with high frequency (15–17 times) at the four internal sites]. The numbers indicate representative residue positions along the backbone of the lysozyme molecule. Reprinted with the permission of Cambridge University Press from Zhang & Matthews (1994). active site (Weaver & Matthews, 1987). The other two play a structural role at the protein core. Other than the four buried water molecules, the most conserved water sites appear at the active-site cleft between the two domains and at the N-termini of α-helices. As is the case in the previous works reviewed above, the 20 most conserved water sites appear in well conserved protein environments and generally have low temperature factors. Buried or highly conserved water molecules also tend to make at least three hydrogen bonds with protein atoms or other water molecules. The less-conserved water sites appear more randomly on the protein surface and are strongly influenced by the particular crystal environment in which the structure was solved.

23.5.4.2.3. Ribonuclease T1

A group of four crystal structures of ribonuclease T1 in complex with guanosine, guanosine-2′-phosphate, guanylyl-2′,5′-guanosine and vanadate were used for an analysis of conserved water positions that contribute to the structural stabilization of the protein (Malin *et al.*, 1991). The four structures were obtained from isomorphous crystals and ranged in resolution from 1.7 to 1.9 Å. Conserved water molecules were considered to be those found within a sphere of 1 Å from each other in all four structures. All other water molecules were excluded from the analysis. 30 water molecules were found to be conserved. Of these, ten were observed near crystal contacts, although only one appears to be dictated by the crystal contact itself, making a single hydrogen bond with each of the symmetry-related protein molecules. Ten other water molecules form a channel that brings together an α-helix and a hairpin-like loop structure and then go on to wrap around the calcium ion, providing half of its coordination sphere. The first five of these water molecules are completely buried, holding together the two secondary-structure elements, which would otherwise collapse (Malin *et al.*, 1991). Two water molecules are found to stabilize the N and C termini, which are brought together by a disulfide bond. The remaining eight conserved water molecules hold together various elements of secondary structure or are located in the active site.

An interesting extension to this study included four additional structures: the E58A mutant in complex with guanosine-2′-monophosphate, the H92A mutant crystallized under two different conditions and wild-type RNase T1 in complex with guanosine-3′,5′-biphosphate. Two of these crystal forms were not isomorphous with the native protein crystals or with each other. Thus a total of eight structures solved in three different space groups were analysed (Pletinckx *et al.*, 1994). Although the effect of crystal packing on the three-dimensional structure of the protein is minimal, there are some significant differences in the solvent structure. In particular, there is no evidence of the calcium-binding site and its coordinating water structure in any crystal forms other than the canonical wild type. Instead, the E58A mutant has a sodium-binding site at a different position, along with three previously unobserved water molecules. It is clear that the presence of the metal ions is fortuitous and linked to the crystallization conditions.

There are 25 water molecules structurally conserved throughout the different packing arrangements studied. Ten of these are single sites, there are three clusters of two water molecules and a larger cluster originally described by Malin *et al.* (1991) to hold together the core of the protein. As was observed for the study on T4 lysozyme (Zhang & Matthews, 1994), the strictly conserved water-binding sites present in crystal structures solved across different space groups are involved in bridging protein secondary-structure elements and seem to be crucial for the integrity of the protein structure.

23.5.4.2.4. Ribonuclease A

Ribonuclease A is not homologous to ribonuclease T1 in either sequence or structure, but both have evolved to catalyse the same reaction with specificity for different substrates (compare Figs. 23.5.4.10 and 23.5.4.11). Ribonuclease A cleaves RNA after pyrimidines, while ribonuclease T1 cleaves specifically after guanine. Therefore, the information obtained from a study of the solvent structure in ribonuclease A is completely independent from that described above for ribonuclease T1. A collection of ten crystal structures of ribonuclease A, derived from five different crystal forms, were compared pairwise after least-squares superposition (Zegers *et al.*, 1994). Seventeen conserved water molecules were found to be within a sphere of 0.5 Å of each other in all of the ten structures and are shown in Fig. 23.5.4.11. These water molecules were found in small clusters of two or three or as part of a larger solvent network. Not surprisingly, they form multiple hydrogen bonds with the protein and generally have low temperature factors. Of the 17 structurally conserved sites, 13 are associated with one of the three α-helices. Most of these link the helices to one of the β-strands. Three water molecules are involved in hydrogen bonding with unpaired amido and carbonyl groups on the protein, and one is found on top of the β-pleated sheet. These interactions result in bringing together elements of secondary structure and in stabilizing distortions within these elements. Conserved water molecules are also responsible for bridging the N-terminal helix to the C-terminal β-strand, which form the two halves of the active site. Conserved water molecules in the active site of ribonuclease A have more recently been analysed using multiple solvent crystal structures (Dechene *et al.*, 2009).

23.5.4.2.5. Protein kinase A

The comparative study of water molecules in seven different protein kinase A structures in complex with different ligands focused exclusively on the active site (Shaltiel *et al.*, 1998). All of the structures were solved from isomorphous crystals to resolutions ranging from 2.0 to 2.9 Å. The more lenient cutoff of 1.5 Å for the radius of the sphere within which the conserved water molecules must be found among the different structures is consistent with the relatively low resolutions of the structures included in this study. The group of structures represents the open, the closed and an intermediate conformation of the catalytic kinase domain. There is a set of six conserved water sites in the active site, in addition to the ATP molecule and the magnesium ion. The conserved water molecules coordinate to ATP, the metal ion and a conserved Tyr residue from the carboxyl terminus of the protein. Thus, the active site consists of an extended network of interactions that weave together both domains of the core, with water molecules playing an integral role in maintaining the structural features important for catalysis. Many of these water molecules associate directly with the inhibitors. In addition, five water sites are observed in positions that would be occupied by substrates or substrate analogues. These water molecules are displaced by ligand oxygen atoms that can compensate for the water hydrogen-bonding interaction with the protein.

23.5.4.3. Summary

Water molecules associated with proteins can be divided between those that are conserved as a result of their functional significance and those that are partially conserved or not conserved at all. The conserved water molecules are generally classified as buried or channel (by a variety of criteria). They tend to be present in the clefts between domains, are critical components of active sites, or bridge between secondary-structure elements. The water molecules that are not conserved occupy hydration sites with favourable hydrogen-bonding characteristics, where the presence of a water molecule is not essential for the structural or functional integrity of the protein.

The displacement of water molecules by organic solvent molecules in the elastase work described above showed that most displaced waters are those classified as surface or crystal-contact waters (Mattos *et al.*, 2006). In the three cases where a buried water molecule was displaced, an alcohol hydroxyl oxygen was found to replace the protein–water hydrogen-bonding interactions. This is analogous to the active-site water molecule in the HIV aspartate protease that gets replaced by a carbonyl group of a potent cyclic urea inhibitor (Lam *et al.*, 1994). In these situations, release of a tightly bound water molecule is entropically favourable, and its enthalpic interactions with the protein are compensated by similar protein–ligand interactions.

The effect of crystal contacts on the water structure was clearly illustrated in the T4 lysozyme work (Zhang & Matthews, 1994). The internal structurally conserved water molecules are unaffected by crystal contacts. Conversely, any of the surface water sites are potentially available either to be replaced by or to mediate crystal contacts, as 95% of the T4 lysozyme surface is involved in a crystal contact when all ten crystal forms are taken together.

23.5.5. The classic models: small proteins with high-resolution crystal structures

Crambin and BPTI are among the handful of proteins for which X-ray crystal structures have been obtained to 1 Å resolution or better. In general, these proteins are relatively small (BPTI, the largest in this group, has 58 amino-acid residues) and often contain at least one disulfide bond. These high-resolution crystal structures have provided structural information beyond that available for larger proteins, particularly with respect to the surface solvent structure. The available detail and precision of the structures, as well as their small size, make them ideal models in computational studies of protein energetics and dynamics. Both crambin and BPTI were used during the pioneering years of protein molecular-dynamics calculations. In this section, special attention is given to crambin and BPTI as representative proteins for which very high resolution structures are available. Focus is on the features of solvent structure that are not available for other proteins.

23.5.5.1. Crambin

Crambin is a plant-seed hydrophobic protein of unknown function. It contains 46 amino-acid residues and was reported to form crystals that diffract to 0.88 Å resolution (Teeter & Hendrickson, 1979). The crystal structure of crambin was determined to 0.945 Å resolution directly from anomalous scattering by the six sulfur atoms involved in three disulfide bonds (Hendrickson & Teeter, 1981). Crambin is an amphipathic molecule in that the hydrophilic components (including six charged groups) are segregated from a mainly hydrophobic surface.

A total of 64 water molecules and two ethanol molecules were located in the electron-density map, despite the fact that the structure was determined in 60% ethanol. The overwhelming number of water molecules compared to ethanol is consistent with the results of the multiple-solvent crystal structures experiments described above for elastase (Mattos *et al.*, 2006).

Most of the 64 water molecules found in crambin interact with polar side chains in the typical manner described previously. The unusual information about solvent structure offered by the

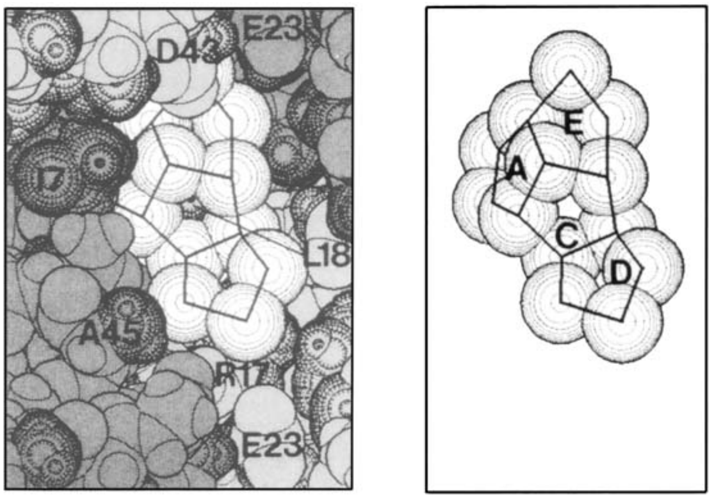

Figure 23.5.5.1
van der Waals surface diagram of the water pentagons A, C, D and E in crambin viewed in the negative **a** direction. Rings A, C and E form a cap around leucine 18. Hydrophobic atoms are shown as dark circles, and water oxygens are shown as light circles. The methyl group of leucine 18 can be seen through the C ring. Adjacent translationally related molecules are shaded. The van der Waals radii used for the protein C, N and O atoms are 1.7, 1.4 and 1.4 Å, respectively, and for water oxygen, 1.8 Å. The larger radius is used for the water oxygens because hydrogen atoms have been omitted. Reprinted with the permission of the author from Teeter (1984).

crambin model is that the arrangement of water molecules around hydrophobic residues is similar to that observed for clathrate hydrate structures (Teeter, 1991). Pentagonal water rings are observed to cap the Cδ2 atom of Leu18 as well as the hydrophobic methylene groups of Arg17 (Teeter, 1984, 1991). The set of five connected water rings is shown in Fig. 23.5.5.1. This ring cluster extends toward the protein, forming heterocyclic rings that are described in detail in the original article (Teeter, 1984).

Although crambin provides the clearest example of pentagonal water rings on a hydrophobic protein surface, it is not the only one. Other high-resolution crystal structures (better than 1.4 Å), such as insulin and cytochrome *c*, have also revealed pentagonal rings, but never to the extent seen in crambin (Teeter, 1984). This is very likely to be a general mode of interaction between water and hydrophobic moieties, be it in inorganic, organic, or biological molecules. The fact that it is not observed in protein structures in general may be related to the lower resolution of most X-ray structures, where it is not possible to model the more disordered areas where these patterns are likely to be found.

23.5.5.2. Bovine pancreatic trypsin inhibitor

Bovine pancreatic trypsin inhibitor (BPTI) is a protein of 58 amino-acid residues whose X-ray crystal structure was obtained in the original crystal form to 1.5 Å resolution (Deisenhofer & Steigemann, 1975). Subsequently, 1 Å X-ray data were obtained from a different crystal form, and the new model was jointly refined with 1.8 Å neutron diffraction data (Wlodawer *et al.*, 1984). Minor differences in structure between the two crystal forms of BPTI were observed (Wlodawer *et al.*, 1984). The interesting contribution of the 1 Å model to the understanding of solvent structure resulted from the ability to refine occupancy at this resolution. A total of 63 water molecules were placed in the model, 20 of them within 1 Å of a water molecule found in the structure solved in the original crystal form. During refinement against the 1 Å data set, full occupancy was assigned to all protein atoms, and water occupancy was allowed to refine. Of the 63 water-molecule positions, 29 were found to be fully occupied. The remaining 34 had partial occupancies, with 0.4 being the minimum occupancy found. Given that there are very few contacts between protein molecules in the crystal (Wlodawer *et al.*, 1984), it is reasonable to assume that this observation is representative of water occupancies on protein surfaces in general. It is likely that well over half of the water positions found on protein surfaces are less than fully occupied, although there is no definitive proof that this is true.

23.5.5.3. Summary

In general, small proteins serve as important models through which more precise details of protein–water interactions can be obtained due to the very high resolution to which their structures can be solved. With respect to understanding solvent structure, the two major contributions of these very high resolution protein models are the observation of solvent structure around hydrophobic residues, where at lower resolution the water molecules 'look' disordered, and a glimpse at the pattern of water occupancy likely to occur on protein surfaces.

23.5.6. Water molecules as mediators of complex formation

The examples given in Section 23.5.4 illustrate two important roles played by water molecules at the binding sites of proteins: as structural water molecules and as displaceable water molecules. As a structural part of a binding site, water molecules are found to be strictly conserved. They are either involved in stabilizing the coming together of secondary-structure elements in a way that appropriately shapes the binding site, or they fill grooves on the protein surface, making it more specific for a given ligand. The second role involves the presence of less tightly bound, partially conserved water molecules that get displaced by the ligand upon binding. In the few examples where tightly bound water molecules are displaced by a ligand, the hydrogen-bonding interaction of the water with the protein is replaced by an atom on the ligand. A third role, not yet discussed, of water molecules in protein active sites is in the catalytic mechanism of enzymatic reactions. An extensive network of water molecules near the active site of serine proteases has been implicated in the catalytic mechanism of these enzymes (Meyer *et al.*, 1988; Meyer, 1992). If this hypothesis is indeed correct, it provides a good example of the cooperation between water molecules and protein atoms in the optimization of function. Unfortunately, it is difficult to explicitly detect catalytic water molecules crystallographically, due to the long data-collection time relative to a catalytic event. However, the development of time-resolved Laue diffraction methods has provided a view of the catalytic water molecule in some proteins, *e.g.* trypsin (Singer *et al.*, 1993), and progress is likely to continue in this area. This section focuses on a few particular examples of how water molecules mediate the formation of complexes, either in the active sites of enzymes or in the binding interface between macromolecules or protein–ligand complexes.

23.5.6.1. Antigen–antibody association

The X-ray crystal structures of the Fv fragment of the monoclonal antibody D1.3 and the structure of its complex with hen egg-white lysozyme were both solved to 1.8 Å resolution (Bhat *et al.*, 1994). This study revealed a significant number of water molecules contributing to the chemical complementarity at the antigen–antibody interface. There are 23 water molecules at the antigen-binding site of the free antibody fragment, while 48 are present mediating complex formation. Seven water molecules are in equivalent positions in the free and complexed antibody (within 1.5 Å). There is no net loss of water molecules at the combining site. In fact, the total number of water molecules at the antigen–antibody interface is not less, but more, than the sum of those in the free antibody combining site and in the antigenic determinant. Furthermore, there is a general decrease in *B* factors of the binding-site residues upon complex formation, implying a decrease in entropy (Bhat *et al.*, 1994). The structural results indicate that water molecules at the antigen–antibody interface play a variety of important roles. Some form an integral part of the binding site, fine-tuning the shape and charge complementarity of the interaction. Others are found to be displaced during complex formation, and still others are unique to the complex, bridging between the two molecules in a variety of locations throughout the complex interface.

The structural analysis correlated well with results of calorimetric experiments that showed that complex formation is enthalpically driven, with an unfavourable entropic contribution (Bhat *et al.*, 1994). The authors suggest that water molecules play a central role in mediating complex formation and claim that the hydrophobic effect is not important in this case. This is an argument that goes contrary to the idea that affinity is contributed by hydrophobic interactions within a relatively small portion of the interface between the interacting molecules, with hydrogen-bonding and charge–charge interactions contributing primarily to specificity (Hendsch & Tidor, 1994; Clackson & Wells, 1995; Hendsch *et al.*, 1996).

23.5.6.2. Protein–DNA recognition

The *trp* repressor binds specifically to the target DNA sequence ACTAGT, resulting in the transcriptional control of L-tryptophan levels in bacteria. The crystal structure of the *trp* repressor/operator complex was solved to 1.9 Å resolution (Otwinowski *et al.*, 1988). Although the structure revealed hydrogen-bonding interactions between the protein and the backbone phosphate groups, no direct hydrogen bonds or non-polar contacts between the protein and DNA bases were observed. Specificity was therefore attributed to the effect of the sequence on the geometry of the phosphate backbone and to water-mediated polar contacts between protein atoms and specific DNA bases. To confirm this hypothesis, the 1.95 Å resolution crystal structure of the free decamer CCACTAGTGG was obtained, containing the recognition six-base-pair sequence (Shakked *et al.*, 1994). A comparative analysis of the free and complexed DNA showed that, when bound to the *trp* repressor, the six-base-pair region is bent by about 15° so as to compress the major groove, with concomitant expansion of the minor groove relative to the uncomplexed DNA (Shakked *et al.*, 1994). However, both free and complexed DNA are underwound, with 10.6 base pairs per turn, rather than the usual 10.0 base pairs per turn. This feature is presumably a result of the particular DNA sequence and is thought to decrease the energy barrier for the binding interaction with the *trp* repressor protein (Shakked *et al.*, 1994). Another specificity component suggested by the authors is conferred by the hydration of the consensus bases. Ten water molecules are observed to interact in the major groove at similar positions in both the free and complexed DNA. Three of these mediate in four hydrogen-bonding interactions to the protein in the complex. Interestingly, the DNA bases to which these three water molecules are bound are among the most conserved and mutationally sensitive bases of the operator. In effect, these three water molecules can be regarded as extensions of the DNA bases and part of the specific recognition elements of the target DNA sequence (Shakked *et al.*, 1994).

The idea of water molecules as mediators of interactions conferring specificity in protein–DNA associations is further supported by the co-crystal structure of the HNF-3/fork head DNA-recognition motif in complex with DNA, solved to 2.5 Å resolution (Clark *et al.*, 1993). Although the lower resolution of this protein–DNA complex may limit the unambiguous determination of water molecules to those that are tightly bound, a series of water molecules are observed in the major groove, bridging specific DNA bases to amino-acid side chains in one of the α-helices of the protein. In this case, direct hydrogen bonding between DNA bases and protein side chains also exists.

The involvement of water in specific protein–DNA recognition was further confirmed in a study of the accuracy of specific DNA cleavage by the restriction endonuclease *Eco*RI under different osmotic pressures (Robinson & Siglar, 1993). Changes in osmotic pressure, resulting from changes in osmolite concentrations, have direct effects on the number of water molecules associated with macromolecules (Rand, 1992). The *Eco*RI experiments show that water activity affects site-specific DNA recognition, with an increase in osmotic pressure leading to a decrease in accuracy of protein–DNA recognition, as observed by DNA cleavage at sites containing an incorrect base pair (Robinson & Siglar, 1993). The results of this study strongly imply a role for one or more water molecules in recognition of specific sequences of DNA. The authors suggest that water mediation may constitute a general motif for sequence-specific DNA recognition by DNA-binding proteins (Robinson & Siglar, 1993).

The role of water molecules as mediators of sequence-specific DNA recognition may be a general motif, but not a necessary one. The solution NMR structure of the complex of erythroid transcription factor GATA-1 with the 16-base-pair DNA fragment GTTGCAGATAAACATT, containing the recognition sequence, shows that the specific interactions between GATA-1 and the major groove of the DNA are dominated by van der Waals interactions hydrophobic in nature (Omichinski *et al.*, 1993). Furthermore, NMR experiments designed to identify the location of water molecules in the complex detected clusters of water molecules bridging the protein to the DNA phosphate backbone, but showed that water was excluded from the hydrophobic interface between the protein and the DNA bases (Clore *et al.*, 1994). Although many of the existing crystal structures of protein–DNA complexes support the general view that water molecules are often integral components of the specific recognition between the protein and the target DNA, this solution structure provides an important example of exclusion of water molecules from the specificity determinants. In the GATA-1–DNA complex, however, water molecules do mediate non-specific binding of the protein to the DNA backbone. It appears, not surprisingly, that water molecules play a variety of roles in the mediation of protein–DNA interactions and that these roles are specific to each particular case.

23.5.6.3. Cooperativity in dimeric haemoglobin

The X-ray crystal structures of liganded and unliganded dimeric haemoglobin from *Scapharca inaequivalvis* have revealed that water molecules at the dimer interface form an

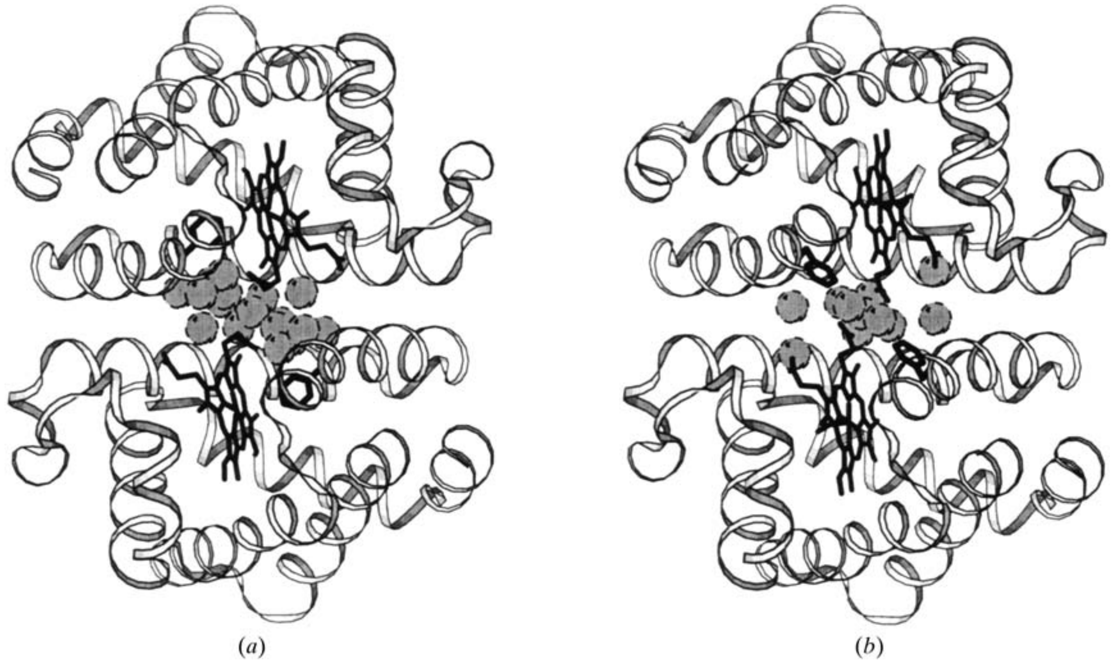

Figure 23.5.6.1
Scapharca HbI interface water molecules. (*a*) Deoxy-HbI at 1.6 Å resolution (PDB code 3SDH) and (*b*) HbI-CO at 1.4 Å resolution (PDB code 4SDH). Included is a ribbon diagram showing the tertiary structure of each subunit, bond representations for the haem group and Phe97 side chain, and spheres representing the approximate van der Waals radii of oxygen atoms for core interface water molecules. Note the cluster of 17 ordered water molecules in the interface of deoxy-HbI for which Phe97 is packed in the haem pocket. Upon ligation, by either CO or O_2, Phe97 is extruded into the interface and disrupts this water cluster, expelling six water molecules from the interface. These plots were produced with the program *MOLSCRIPT* (Kraulis, 1991). Reprinted with permission from Royer *et al.* (1997). Copyright (1997) The American Society for Biochemistry & Molecular Biology.

integral part of the cooperativity mechanism in this system (Condon & Royer, 1994; Royer, 1994). The binding of oxygen to one of the monomers causes little rearrangement of quaternary structure. It does, instead, displace the side chain of Phe97 which, in the low-affinity deoxy form, packs in the haem pocket (Royer *et al.*, 1990). Phe97 in the deoxy form lowers the oxygen affinity by restricting movement of the iron atom into the haem plane (Royer, 1994). Upon oxygen binding, Phe97 flips to the dimer interface, removing six out of the 17 water molecules that are found in the deoxy form (Fig. 23.5.6.1). The resultant destabilization of the water clusters found between the two subunits facilitates the flipping of Phe97 in the other subunit, with a concomitant increase in oxygen affinity of the haem in the second subunit (Pardanani *et al.*, 1997; Royer *et al.*, 1997).

In each of the monomeric subunits, Thr72 is positioned to form a hydrogen bond with a water molecule at the periphery of the deoxy dimer interface (not shown in Fig. 23.5.6.1). In effect, this interaction caps the water cluster on either side of the interface, presumably helping to stabilize these well ordered water molecules. The isosteric mutation Thr72 to Val was designed to test the importance of this interaction to the stability of the water cluster in the low-affinity haemoglobin dimer and the resultant effect on ligand affinity and cooperativity (Royer *et al.*, 1996). The crystal structure of the T72V mutant was solved to 1.6 Å resolution. This crystal structure reveals that the only significant difference between the mutant and wild-type proteins is the loss of the two water molecules that directly hydrogen-bond to Thr72 in each of the wild-type subunits. Furthermore, there is a significant increase in both activity and cooperativity resulting from the mutation (Royer *et al.*, 1996). The authors conclude that, as a result of the mutation, the loss of two water molecules in the interface cluster is sufficient to alter the balance between the low- and high-affinity forms of the protein. This result demonstrates that water molecules are key mediators of information transfer between the haems in the two subunits in dimeric haemoglobin and that their precise positioning and interactions with protein atoms are crucial in maintaining the chemical balance required for biological function.

23.5.6.4. *Summary*

The few examples illustrated above provide diverse views of the ways in which Nature can use water molecules as integral parts of macromolecular interactions. Water molecules can be involved in specificity and recognition, in thermodynamics of binding and affinity, in the cooperative behaviour of allosteric proteins, and in catalysis. Not only do the specific examples illustrate general roles possible for water molecules in the context of a given type of macromolecule, such as proteins or nucleic acids, but they are often representative of any macromolecular system. For example, the role of water in recognition and specificity illustrated above for protein–DNA interactions has also been observed in the L-arabinose-binding protein interaction with specific sugar molecules (Quiocho *et al.*, 1989). Clearly, water molecules are involved so intimately, and in so many different ways, with the formation of molecular complexes that it is not possible to understand the formation process and the function of the complex without taking into account the role of this universal solvent.

23.5.7. Conclusions and future perspectives

The aim of this chapter was to provide a general overview of the available crystallographic information on the roles of water molecules in their interactions with macromolecules. To achieve this aim, the focus has been on representative examples rather than an exhaustive review of the literature. The classification of water molecules according to location and frequency of occurrence among related proteins, or independently solved crystal structures of a given protein, is a crucial element in determining their functional roles.

It has become clear that water molecules involved in crystal contacts can occur virtually anywhere on the protein surface, as exemplified in the case of T4 lysozyme, and that they have properties similar to the majority of surface water molecules within the context of the crystal. Therefore, it is possible to conclude that for the majority of cases, the crystal contacts between proteins involved in the various studies discussed in this review do not significantly influence the general conclusions drawn.

Water molecules bind to proteins so as to satisfy the hydrogen-bonding potential of protein atoms that are not part of the intramolecular hydrogen-bonding pattern within the native structure. At the primary level, the hydrogen bonding is such as to follow the stereochemical requirements of the individual atom in question, in a manner similar to that occurring for the same atom in small molecules. At the secondary-structure level, these positions tend to provide extensions of α-helices or β-sheets as well as to solvate protein atoms in exposed turns. At the tertiary level, they occur more favourably in grooves or cavities within the protein.

Internal or buried water molecules are found to bridge between domains of a single monomer or bring together different secondary-structure elements within a given domain. They have also been observed in the binding sites of proteins where they fine-tune the shape or electrostatic complementarity towards the substrate or ligand. In general, buried water molecules occur in cavities within the protein, making multiple hydrogen bonds with protein atoms that are likely to be conserved among members of a given family. These water molecules are themselves conserved and must be considered an integral part of the protein architecture. They are often connected to bulk water through water channels leading to the protein surface.

Surface water molecules play important roles in protein dynamics, catalysis, thermodynamics of binding, and in mediation of cooperativity, metal binding, recognition and specificity. Representative examples of water molecules in each of these different roles are discussed in the present review. Some of the surface water molecules are found to be conserved within families of proteins, particularly when they are involved in one of the specific roles mentioned above.

In addition to the commonly observed features in crystal structures of proteins solved to around 2 Å resolution, the crystal structures of crambin and BPTI, both solved to 1 Å resolution, provide examples of the type of information only available at very high resolution. This includes the arrangement of water molecules into pentagonal rings around hydrophobic side chains and the occupancy of water molecules on protein surfaces.

A cohesive picture has emerged of the locations of well ordered water molecules on protein surfaces and their functional roles. Currently, there is a good structural view of the protein atoms as well as of the structure of water molecules associated with the protein. The question now is how this information can be used in predicting *a priori* where water molecules will be involved in important structural or functional roles. While having information on the ordered water molecules associated with protein surfaces represents significant progress toward the ultimate goal of understanding the global thermodynamic and kinetic picture of molecular processes in water, the entire system is still not understood. For instance, how does the bulk water influence the dynamic and thermodynamic processes in which the protein and ordered water molecules are involved? Furthermore, what is the importance of solutes normally found in the biological environment where proteins and other macromolecules exert their function? Knowledge must continue to expand toward an understanding of the complete system. Meanwhile, the present models can go a long way toward successful practical applications in protein engineering and ligand design. In order to improve these models, the information accumulated so far can be combined with empirical results and theoretical models to expand the understanding of the first principles underlying biological processes. Building the bridge between empirical observation and first principles is an iterative process still in its infancy.

We wish to thank Martin Karplus and Gregory A. Petsko for years of support and discussions that ultimately contributed to the integrity of this review. During the writing of this review Carla Mattos was supported by the American Cancer Society Postdoctoral Fellowship grant No. PF-4331.

Chapter 23.6. Halogen interactions in biomolecular crystal structures

M. J. Vallejos, P. Auffinger and P. S. Ho

23.6.1. Introduction

Halogens are uncommon substituents in biological molecules. It is not surprising, therefore, that molecular interactions involving covalent halogen compounds are not foremost in the minds of most biologists. There is, however, an increasing appreciation that halogenated compounds play important roles in biology, starting with the naturally halogenated hormone thyroxine (Fig. 23.6.1.1*a*) (Wojtczak *et al.*, 2001), and extending to bioactive secondary metabolites isolated as natural products (Gribble, 2004) and a growing list of synthetic compounds that serve as inhibitors against a broad range of enzymes. Proteins and nucleic acids are naturally halogenated through oxidative processes associated with inflammatory response mechanisms (van Pée & Unversucht, 2003; Shen *et al.*, 2001), with chlorinated and brominated amino acids in proteins correlated with various respiratory ailments and allergic responses (Buss *et al.*, 2003; Wu *et al.*, 2000). In structural biology, it is now common to add electron-rich halogens (particularly Br and I) to help solve the phase problem in crystallography, or magnetically active nuclei (^{19}F) to facilitate structure determination by NMR. In nucleic acids, halogenated nucleotide bases can be incorporated in synthetic oligonucleotides to help determine the structures of DNA and RNA, as well as of protein–nucleic acid complexes. Halogenated amino acids such as bromophenylalanine can now be introduced site-specifically into proteins through *in vivo* incorporation (Wang *et al.*, 2006), which can also facilitate phasing of X-ray diffraction data for protein crystals (Xie *et al.*, 2004), while synthetic fluorinated amino acids have been used to facilitate structural studies by ^{19}F NMR (Hammill *et al.*, 2007). Together, these various systems have contributed to the recent growth in the number of halogens and halogen interactions observed in biomolecular structures.

For this particular discussion, we will focus on the molecular interactions of halogenated compounds seen in structures determined by single-crystal X-ray diffraction rather than by NMR, primarily because of the strong dependence on the distance and angle relationships required to categorize and understand such interactions (NMR structures are highly dependent on appropriate force fields to define conformation; unfortunately, current force fields do not properly treat interactions involving halogens). A survey of the 16 June 2009 release of the Protein Data Bank (PDB; Berman *et al.*, 2000) showed that there were 2670 entries containing a halogen atom (Table 23.6.1.1). In other words, nearly 5% of the more than 58 000 entries from this release contained at least one covalent halogen, indicating that halogens are an important component in biomolecular structures.

23.6.2. Classical treatment of halogen interactions

23.6.2.1. Non-specific hydrophobic effects

Halogen interactions in proteins and nucleic acid structures have classically been treated non-electrostatically. Indeed, most quantitative structure–activity relationships (QSARs) consider only the steric and lipophilic contributions of halogens when trying to predict their effect on ligand binding. The majority of interactions can be classified in this sense; non-electrostatic interactions would predict distances between halogen and other non-hydrogen atoms to be greater than or equal to the sum of their respective van der Waals radii ($\sum r_{\rm vdW}$), with the halogen atoms sitting in hydrophobic pockets. An example of this is seen in the binding of dibromomethane to methane monooxygenase hydrolase (Egner *et al.*, 2005), where the Br atoms of the bound ligand are surrounded primarily by the hydrophobic side chains (Leu, Val and Phe) of the protein (Whittington *et al.*, 2001). The non-electrostatic components of molecular halogens can be characterized by the size (as measured by $r_{\rm vdW}$) and hydrophobicity (as measured by the difference in partition coefficients and the associated molecular solvation free energy for the accessible surface) of the respective halogen atoms (Table 23.6.2.1).

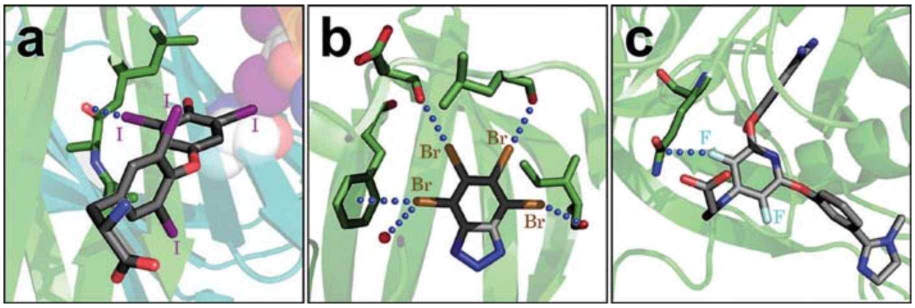

Figure 23.6.1.1
Examples of electrostatic interactions of halogenated ligands with proteins. The C atoms of the protein residues are shown in green and those of the bound ligands in black. (*a*) An I atom from tetraiodothyroxine (violet) is shown with its close (3.07 Å) *X*-bonding interaction (blue dots) to the carbonyl O atom of Ala109 of transthyretin (Wojtczak *et al.*, 2001). (*b*) The Br atoms (orange) of tetrabromobenzotriazole form short contacts to the carbonyl O atoms of Glu81 (3.0 Å), Leu83 (2.9 Å) and Ile10 (3.3 Å), and to the aromatic ring of Phe80 (3.5 Å to the centre), of phospho-CDK2/cyclin A (De Moliner *et al.*, 2003). There is an additional interaction with a water molecule (2.91 Å). (*c*) An F atom (cyan) from the inhibitor ZK-807834 interacts with the amide C atom of the Gln192 side chain in the ligand-binding site of the clotting factor Xa (Adler *et al.*, 2000).

23.6.2.2. Substituent effects

The classical approach to the electrostatic effects of halogens is to consider them as electron-withdrawing substituents: I, Br, Cl and F atoms are strong electron-withdrawing groups, relative to hydrogen, in their effects on the reactivities of *para*- and *meta*-substituted benzoic acids [reflected in the so-called Hammett σ constants (Hammett, 1937), Table 23.6.2.1]. However, such substituent effects do not tell us anything about how halogens themselves participate in directing non-covalent interactions. Our basic understanding is that halogens are electron-rich and therefore we would expect them to act as Lewis bases, serving, for example, as hydrogen-bond acceptors (like carbonyl O or

Table 23.6.1.1
Interactions in crystal structures in the Protein Data Bank

The numbers of interactions (N_I) for molecular halogens with oxygen (O), nitrogen (N), sulfur (S) and carbon atoms (C) are tabulated for single-crystal structures at resolutions of 3.0 Å or better from the 16 June 2009 release of the PDB (containing 58 236 total entries). A contact is considered to be an interaction if the distance between the halogen and its partner is between 2.2 Å and the van der Waals contact distance ($D_{\max}$†). O-atom partners are counted separately for non-water and water interactions, while interactions with non-aromatic atoms are counted separately from those involving aromatic atoms.

	F		Cl		Br		I	
Acceptor atom	$D_{\max}$ (Å)	N_I	$D_{\max}$ (Å)	N_I	$D_{\max}$ (Å)	N_I	$D_{\max}$ (Å)	N_I
Non-aromatic (backbones of polypeptides and polynucleotides, or side chains of non-aromatic amino acids)								
O (non-water)	2.99	1219	3.27	241	3.37	198	3.50	285
O (water)	3.52	1454	3.80	263	3.90	1110	4.03	637
N	3.02	977	3.30	206	3.40	78	3.53	139
S	3.27	45	3.55	39	3.65	13	3.78	16
C	3.17	1466	3.45	511	3.55	338	3.68	472
Aromatic (side chains of Phe, Tyr, Trp and His in proteins, and the bases of nucleotides)								
O	2.99	42	3.27	22	3.37	58	3.50	8
N	3.02	11	3.30	9	3.40	16	3.53	0
C	3.17	174	3.45	242	3.55	237	3.68	77
Total	5388		1533		2048		1634	

† $D_{\max}$ is the sum of the van der Waals radii [$r_{\rm vdW}$; Bondi (1964)] for the halogen and its interaction partner. In the case of water, this is the sum of the length of the O—H bond (0.98 Å) plus $r_{\rm vdW}$ of the H atom (1.09 Å) and $r_{\rm vdW}$ of the respective halogen. The longer $D_{\max}$ for interactions with water allows the halogens to serve as hydrogen-bond acceptors.

Table 23.6.2.1
Physical properties of molecular halogens

Comparative values are shown for each halogen for their van der Waals radii† ($r_{\rm vdW}$), their contribution to partition coefficients in water *versus* octanol of the respective halobenzene *versus* unsubstituted benzene ($P_{x\varphi}$ and P_{φ}, respectively‡), the associated contributions to the solvation free energies§ (SFEs), and the substituent effects for *para*- or *meta*-substituted benzoic acids, as reflected in the Hammett constants¶ (σ_p and σ_m, respectively).

Halogen (X)	$r_{\rm vdW}$ (Å)	$\log(P_{x\varphi}) - \log(P_{\varphi})$	SFE (cal Å^{-2})	σ_p	σ_m
F	1.47	0.12	11.9	0.062	0.337
Cl	1.75	0.34	13.2	0.227	0.373
Br	1.83	0.84	37.6	0.232	0.393
I	1.98	1.10	41.5	0.276	0.353

† From Bondi (1964). ‡ Defined as the base-10 logarithm of the partition (P) from water to octanol of the halogenated benzene ($X\varphi$, where X is the halogen) minus that of benzene (φ). Partition coefficients from Hansch (1979). § Calculated as $-2.303RT[\log(P_{x\varphi}) - \log(P_{\varphi})]$ divided by the solvent-accessible surface of the halogen in the respective halobenzene model. ¶ From Hammett (1937). Positive values reflect the electron-withdrawing capacity of the substituent.

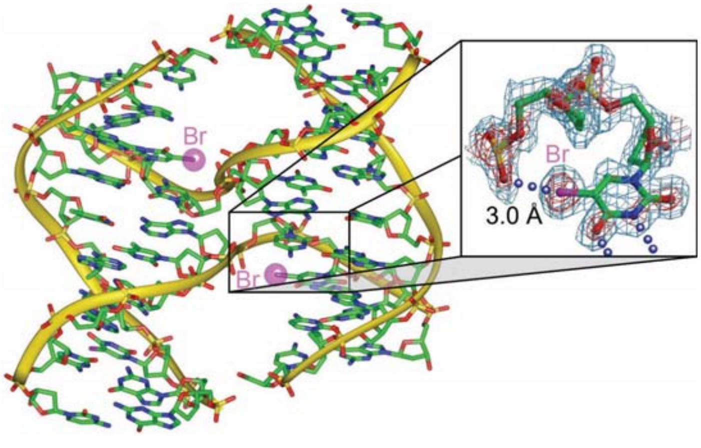

Figure 23.6.3.1
The single-crystal structure of the DNA sequence d(CCAGTAC-brUGG), where brU is 5-bromouracil (Br atom shown as a sphere), as a four-stranded Holliday junction. The inset shows the electron-density map ($2F_o - F_c$ map, contoured at 1.5σ in blue and 3σ in red) around the brU residue, with the short contact between the Br atom and the phosphate O atom at the tight U-turn of the DNA junction backbone indicated.

imine N atoms). Indeed, F atoms can typically replace hydroxyl groups as hydrogen-bond acceptors in carbohydrates (Scott & Viola, 1998; Lougheed *et al.*, 1999; Ly *et al.*, 2000; Hart *et al.*, 2000).

23.6.3. Electrostatic molecular halogen interactions

Non-covalent halogen interactions are recognized as being highly diverse, extending well beyond the classical properties of size, lipophilicity and substituent effects. The remainder of this review will focus on a class of electrostatic interactions called halogen bonds (X bonds) and other similar electrostatic interactions, primarily because these are specific interactions that have been shown to affect molecular conformations and ligand binding in single-crystal structures of proteins and nucleic acids.

23.6.3.1. Biological halogen bonds

The growing use of halogens for crystallographic phasing (halide soaks notwithstanding) and in natural product and drug development means that structural biologists must become more aware of the non-covalent molecular interactions involving the Group VII elements. In many cases, halogens are introduced as ‘neutral’ substitutions, but they are not altogether unobtrusive: there are now several examples where a halogenated nucleotide base has been seen to very dramatically affect the overall structure of DNA. In one such example, a brominated uracil base induced a decanucleotide sequence to crystallize as a four-stranded Holliday junction (Fig. 23.6.3.1), while the analogous unbrominated and methylated sequences crystallized as standard B-DNA double helices (Hays *et al.*, 2003). Although we did not recognize this as an X bond at the time, the Br atom was seen to form a stabilizing interaction with the negatively charged phosphate O atom to force the DNA backbone into a tight U-turn and, as a result, to help form the four-stranded complex. In fact, we and others (Muzet *et al.*, 2003) had thought that such short halogen–oxygen distances represented a completely new type of interaction, until an internet search led to the lecture by Odd Hassel for the 1969 Nobel Prize in Chemistry (Hassel, 1972). In short, there is ‘nothing new under the sun’ [Ecclesiastes 1:9–14].

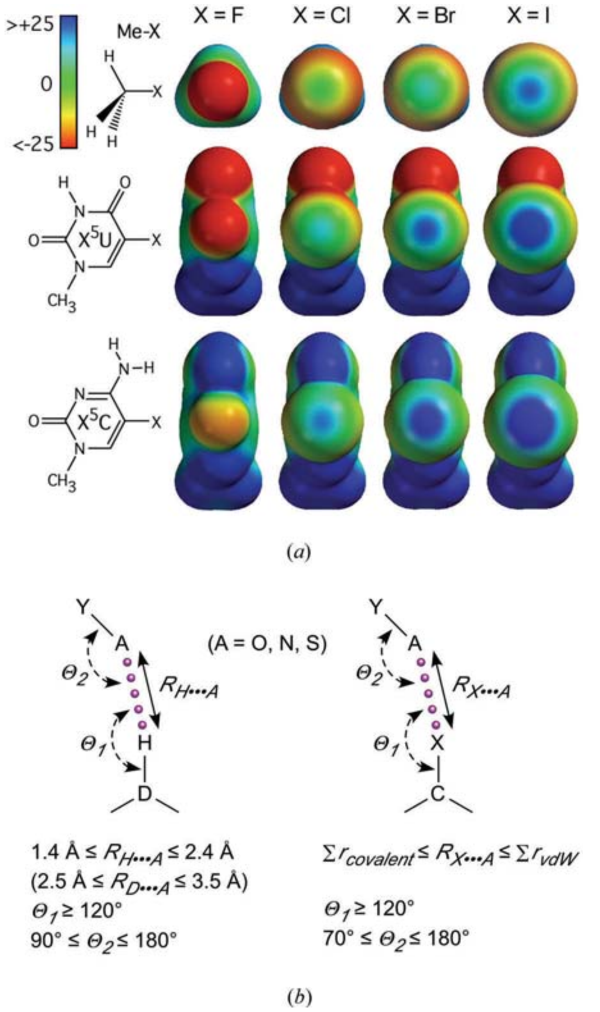

Figure 23.6.3.2
Properties of halogen bonds. (*a*) *Ab initio* calculations on model compounds (halomethane top, 5-halouracil middle, 5-halocytosine bottom) show an increase in polarizability of molecular halogens (X), with I > Br > Cl > F [adapted from Auffinger *et al.* (2004)]. The molecular surfaces are shown looking down the C–X bond, with electropositive and electronegative potentials shown in blue and red, respectively. (*b*) Comparison of the geometries of hydrogen bonds (left) and halogen bonds (right) [adapted from Voth & Ho (2007)]. In each case, the weak interactions are characterized by the distance between the donor (D) and acceptor (A) atoms ($R_{H\cdots A}$ and $R_{X\cdots A}$), which is longer than the sum of the covalent radii ($r_{\rm covalent}$) but shorter than the sum of the van der Waals radii ($r_{\rm vdW}$), and by the defined angles for the approach of the acceptor towards the donor (θ_1) and the donor towards the acceptor (θ_2).

The type of molecular interaction described by Hassel involves halogens serving as Lewis acids rather than as Lewis bases, and has seen a resurgence of interest in materials science. These interactions, initially called 'charge-transfer bonds' (Hassel, 1972), could, for example, draw the Br atoms of the Br_2 molecule to within 2.7 Å of the O atoms in dioxane (~0.5 Å shorter than $\sum r_{\rm vdW}$ of the interacting atoms). This would initially appear to be contrary to the expectation that electron-rich atoms should repel each other, but, as we shall see, halogens are not uniform spheres of electron density. In halogens larger than fluorine, the electron distributions are polarized such that an electropositive crown develops along the covalent (σ) C—X bond (Fig. 23.6.3.2*a*), and it is this 'σ hole' (Politzer, Murray & Lane, 2007) that accommodates the stabilizing electrostatic interactions between a molecular halogen and an electron-rich Lewis base (Fig. 23.6.3.2*b*). Such interactions are now referred to as halogen bonds (or X bonds) to acknowledge their similarities with the better known hydrogen bond (Metrangolo *et al.*, 2005; Metrangolo & Resnati, 2008). We can thus define the X-bond acceptor (by analogy with hydrogen-bond acceptors) as any electron-rich Lewis base, and the X-bond donor as the electropositive crown of the polarized halogen. Although they share similar acceptors (Metrangolo & Resnati, 2001) and, as we will discuss in greater detail, similar energies of interaction, X bonds are more directional than hydrogen bonds (Lommerse *et al.*, 1996).

The 'strength' of the X bond is expected to be dependent on the polarizability of the halogen donor, with I > Br > Cl in both polarizability and X-bonding potential (F atoms are not generally polarizable and therefore not typically considered X-bond donors) (Fig. 23.6.3.2). This is consistent with the understanding that the X bond is primarily an electrostatic interaction, although dispersion and charge transfer do contribute to some extent (Metrangolo *et al.*, 2005). Today, X bonds are exploited in chemistry to control molecular crystallization and supramolecular assembly (Metrangolo *et al.*, 2005; Metrangolo & Resnati, 2008; Politzer, Murray & Concha, 2007).

With this long history and a rekindled interest in applying X bonds for the design and synthesis of new materials (Fourmigué, 2009), it is surprising that this interaction has been largely overlooked in structural biology, but this could be attributed, until recently, to the very limited number of biological structures that included Group VII atoms. In 2004, we surveyed the occurrence of X bonds in the PDB and found 113 unique X-bond interactions in 66 protein–ligand complexes and six nucleic acid structures (Auffinger *et al.*, 2004). The results were dominated by X bonds to O atoms, with carbonyl O atoms of the peptide backbone (Figs. 23.6.1.1*a*,*b*) in protein–ligand complexes representing ~70% of these interactions. A survey of the 2008 PDB entries by Lu *et al.* (2009) found 258 X bonds to O-atom acceptors in the structures of protein–ligand complexes alone. Clearly, X-bonding interactions are important for ligand binding to proteins and this list of X-bonding interactions is expected to grow with the PDB, while becoming more prominent in the literature as the significance of this interaction becomes better recognized. A short Br$\cdots$O X bond is estimated to contribute to a more than 1000-fold increase in selectivity (equivalent to ~4 kcal mol^{-1} in energy; 1 kcal mol^{-1} = 4.184 kJ mol^{-1}) for the binding of an inhibitor by aldose reductase *versus* the related aldehyde reductase enzyme (Muzet *et al.*, 2003). In addition to oxygen, other electron-rich Lewis bases are also seen as X-bond acceptors, including the N atoms of various basic amino-acid side chains (Voth & Ho, 2007) and the S atoms of Cys or Met residues (Liu *et al.*, 2009). Much of the remainder of this discussion will be on the dominant interactions with O-atom acceptors of various types.

The geometry of X bonds provides an understanding of what is involved in the formation and stabilization of X bonds in biological systems. By analogy with the structure of X bonds between small organic molecules (Cody & Murray-Rust, 1984; Lommerse *et al.*, 1996; Ouvrard *et al.*, 2003), the geometry of biological X bonds is characterized by the angles of approach of the acceptor to the halogen donor (θ_1 relative to the C—X bond; Fig. 23.6.3.2*b*) and the halogen towards the base acceptor (θ_2; Fig. 23.6.3.2*b*) (Auffinger *et al.*, 2004). The θ_1 angle is essentially linear, consistent with this being an electrostatic interaction of the base acceptor, with the electropositive crown, or σ hole, being aligned along the C—X bond, as seen previously in organic complexes. The θ_2 angle is ~110–120°, suggesting that the X bonds involve the non-bonding electrons of the acceptor. However, an extended analysis showed that most X bonds in protein–ligand complexes are aligned perpendicular to the

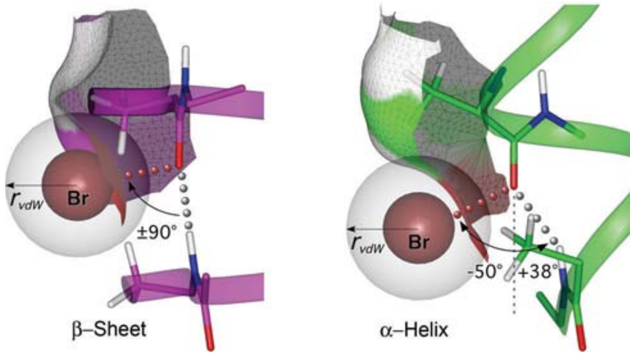

Figure 23.6.3.3
The orthogonal relationship between hydrogen bonds and X bonds that share common carbonyl O atoms as acceptors (Voth *et al.*, 2009), showing the approach of halogens from the ligands towards the carbonyl O atoms of the peptide bonds in ideal models of a β-sheet (left) and an α-helix (right) [adapted from Voth *et al.* (2009)]. In the β-sheet, the hydrogen bond to the shared O atom is oriented in the plane of the peptide bond, allowing the orthogonal X bond to approach from above or below and perpendicular to the plane. In the α-helix, the hydrogen bond is oriented ~40° from the plane and therefore the orthogonal relationship aligns the X bond ~50° from the peptide plane.

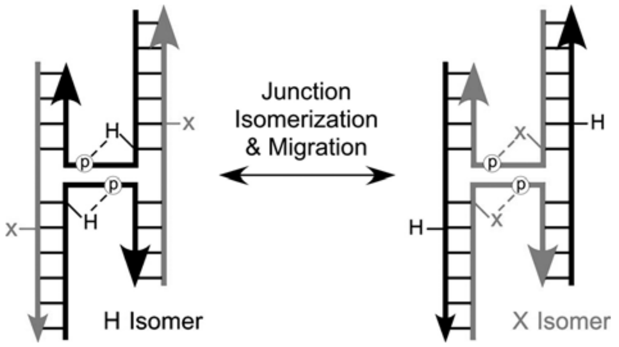

Figure 23.6.3.4
Competition assay to measure the energies of X bonds *versus* hydrogen bonds using a DNA junction (Voth *et al.*, 2007). The junction is constructed by annealing two hydrogen-bonded strands (black) and two X-bonded strands (grey). It is stabilized either by hydrogen bonds from the cytosine bases to the phosphates (labeled 'p') of the crossover DNA strand to form the H isomer (left), or by X bonds from a 5-halouracil at the equivalent position of the X-bonded strand to form the X isomer (right). The distribution of X *versus* H isomers in the crystal structure can be determined by analysing the distribution of halogens on the inside *versus* the outside strands of the junction, which, in turn, can be used to calculate the difference in energy between the X and hydrogen bonds at this position in the DNA junction (assuming that the crystal samples the population in the solution and that the crystal structures for the H and X isomers are nearly identical).

peptide plane, indicating that it is the π- rather than n-electron system that is preferred for X-bonding interactions (Auffinger *et al.*, 2004).

This preference for the π system in biological X bonds is not what would be predicted from surveys of small-molecule structures. In organic complexes, an X bond to a π system is seen rarely and only when there appears to be significant steric crowding that limits access to the X-bond acceptor atom (Ouvrard *et al.*, 2003). We have proposed the concept that X bonds in proteins are orthogonal molecular interactions to hydrogen bonds when they share a common carbonyl oxygen acceptor (Fig. 23.6.3.3) (Voth *et al.*, 2009), with orthogonality referring to both the perpendicular orientation of the shared X and hydrogen bonds and the relative thermodynamic independence of the two interactions. This model suggests that X bonds can be introduced in a well defined geometry to enhance the affinity at a ligand–protein interaction interface without disrupting the structural hydrogen bonds of the protein target. This is potentially a very powerful concept when X bonds are applied as a molecular tool for the rational design and synthesis of new inhibitors and drugs against enzyme targets (Metrangolo & Resnati, 2008).

How strong is a biological X bond? An X bond has been estimated, from *ab initio* calculations and crystallization of organic molecules, to be equivalent to a hydrogen bond in energy. Similar calculations on X bonds to peptide O atoms in protein–ligand complexes suggest that a hydrogen bond has approximately the same energy as an iodine X bond, with I > Br > Cl, as expected from their relative polarizabilities (Lu *et al.*, 2009). This is consistent with the observation that halogenated benzenes can form halogen bonds to the S atom of a Met residue in an artificial pocket engineered into a T4 lysozyme mutant (Liu *et al.*, 2009), but that the energies of these interactions are weak (approximately 0.5–0.7 kcal mol^{-1} more stabilizing than simple van der Waals interactions).

The energies of X bonds *versus* hydrogen bonds in a nucleic acid system have been estimated directly using a crystallographic assay that takes advantage of the conformational isomerization of a DNA Holliday junction (Grainger *et al.*, 1998; Lilley, 1999; McKinney *et al.*, 2003) and the ability of specific hydrogen and X bonds to the phosphate O atoms to stabilize the four-stranded complex (Eichman *et al.*, 2001; Hays *et al.*, 2005, 2003) (Fig. 23.6.3.4). From this set of competition studies, it was determined that a $\text{Br}\cdots\text{O}^{-1/2}$ type X bond is ~2–5 kcal mol^{-1} more stable than a hydrogen bond (Voth *et al.*, 2007). When extended to other halogens, the studies showed that I > Br > H > F (unpublished work). This competition assay also demonstrates that X bonds can be used to control DNA conformation (Voth *et al.*, 2007).

The energies determined for the $\text{C}{-}X\cdots\text{O}^{-1/2}$ X bonds in this DNA system (Voth *et al.*, 2007) are at least four to ten times greater than those estimated for the $\text{C}{-}X\cdots\text{S}$ X bonds in the T4 lysozyme–ligand studies (Liu *et al.*, 2009), and one might ask whether these discrepancies can be reconciled. We suggest that it is the nature of the Lewis-base acceptor that accounts for the dramatic difference, reflecting perhaps the difference between the base strength of an S atom in a thiol ether and that of the formally charged O atom of a phosphodiester. This hypothesis can be tested by comparing the energies of a neutral and a formally charged phosphate O atom. The stabilizing potential of a biological X bond apparently falls within a very broad range from near zero to a value >5 kcal mol^{-1} more stable than a standard hydrogen bond, depending on the polarizability of the donor halogen and the basicity of the acceptor. Thus, X bonds can be applied as a molecular tool that can be tuned energetically to control and drive macromolecular interactions, which can be exploited in synthetic biology for creating new nanomaterials from biological molecules.

Although oxygen, nitrogen and sulfur are the dominant X-bond acceptors, the side chains of aromatic amino acids can also serve as X-bond acceptors (Voth & Ho, 2007). In the specific examples available for ligand complexes with protein kinases, the $\text{C}{-}X$ bonds are oriented perpendicular to the plane and impinge on the centre of the aromatic ring (Fig. 23.6.1.1*b*), similar to hydrogen bonds to aromatic amino acids and cation–π interactions between positively charged and aromatic amino acids (Meyer *et al.*, 2003). The X-bond acceptor, in these cases, would be the delocalized π-electron system of the aromatic side chains. *Ab initio* calculations suggest that the electrostatic contribution to aromatic X bonds is very weak (around 1 kcal mol^{-1} at an optimum distance of 3.6 Å from a Br atom to the centre of an aromatic ring, or ~0.3 Å shorter than the predicted closest van der Waals approach; Voth & Ho, 2007), but hydrophobic effects may enhance the stabilizing potential of this type of interaction geometry.

23.6.3.2. Other halogen-specific electrostatic interactions in biological macromolecules

Specific X-bonding interactions between electropositive σ holes and Lewis-base acceptors are only one class of electrostatic interaction available to halogens. There are other classes that are variations on the same theme, where the halogen serves as a Lewis acid attracted to an electron-rich base, or where the halogen acts as the base attracted to an electrophilic acid. The most obvious example would be an electronegative F atom (which is not polarized) interacting with electropositive atoms. A very clear example of this type of electrostatic interaction is seen in the short contact (2.9 Å) between one F atom of the ZK-807834 inhibitor and the amide C atom of the Gln192 side chain in the ligand-binding site of the clotting factor Xa (Fig. 23.6.1.1*c*) (Adler *et al.*, 2000). We should note that, in addition to creating an electropositive crown, polarization of a halogen will also render the annulus around the σ hole more electronegative. This electronegative ring can serve as a Lewis base to interact with electropositive atoms and is observed in interactions of Cl, Br and I from ligands with the carbonyl C atoms, as opposed to the O atoms of the peptide backbone and various amino-acid side chains (Paulini *et al.*, 2005).

The distinction between X bonds and these other types of electrostatic interaction for any given halogen atom is dependent on the geometry of approach and the electrostatic nature of the atom approaching the halogen. An electronegative base approaching linearly to the C—X bond towards the σ hole would define an X bond, while an electropositive donor approaching perpendicular to the C—X bond would probably not. For example, a survey of short contacts between halogens and aromatic side chains (Saraogi *et al.*, 2003) showed that F atoms were the most commonly seen to interact with His, Phe, Trp and Tyr residues, although I, Br and Cl also show interactions with various geometries. The analysis indicates that fluorine interactions show a single broad distribution for distances from the halogen to the aromatic ring, while the distance distribution for chlorine appears to be bimodal, with one group at very short distances and another at about the van der Waals contact distance. A more complete analysis to correlate the distance–angle relationships may help to distinguish between aromatic X bonds to delocalized π systems and the opposing electrostatic interactions to the more electropositive carbon centres.

23.6.4. Concluding remarks

Halogens show a variety of different types of interaction with atoms in proteins and nucleic acids, and the particular type of interaction depends on both the properties of the halogen and what it is in contact with. It is this variability that may account for the distinct preference for certain halogens to interact with particular types of amino acids in proteins (Kortagere *et al.*, 2008). However, unlike most other interactions there is a strong directionality to molecular halogen interactions, particularly in biological systems, which may specify one type of interaction over another.

If we could fully understand the relationships between the geometries and energies of interactions, the types of electrostatic interaction described here could be exploited in biomolecular engineering in ways that are similar to, and extensions beyond, the principles used to design synthetic materials. We should stress, however, that our understanding of such interactions, particularly of biological X bonds, is still in its infancy. For example, Kraut *et al.* (2009) engineered halogenated phenylalanine residues into ketosteroid isomerase in order to determine whether an X bond could replace a functionally important hydrogen-bond interaction with an oxyanion hole, and found that the halogenated residues behaved similarly to a non-halogenated Phe residue at this functional position. However, close inspection of the model for the X–Phe mutant in this construct suggests that the geometry of approach of the halogen towards the oxyanion may not be the ideal for a particularly strong X bond. Thus, although it is tempting to apply such interactions in rational design strategies, we may simply not have enough understanding yet of the basic underlying principles to exploit these interactions effectively at this time. In another case, formation of the hairpin conformation that forms a kissing-loop structure in the RNA dimerization initiation site (DIS) from HIV-1 was shown to be facilitated by bromination of the uracil at the U3 position, compared with the bromination of uracils at other positions and the non-brominated RNA, which favour the duplex form (Ennifar *et al.*, 2007). The crystal structures of the brominated U3 *versus* other uracils provide no insight into why this particular halogen at this specific position should have such a profound effect on the conformational preference of the RNA.

Still, we would argue that a combination of experimental studies, coupled with *ab initio* and database analyses, will provide detailed understanding of the geometry–energy relationships for the various types of halogen interaction available to biological macromolecules. With this understanding, novel molecular tools can be developed to facilitate the rational design of new and more effective inhibitors against therapeutic targets, to manipulate the conformation and stability of protein and nucleic acid structures in the design of new nanomaterials, and to design new interaction interfaces for protein–protein and protein–nucleic acid complexes in synthetic biology.

PART 24. CRYSTALLOGRAPHIC DATABASES

Chapter 24.1. The Worldwide Protein Data Bank

H. M. Berman, K. Henrick, G. Kleywegt, H. Nakamura and J. Markley

24.1.1. Introduction

The Protein Data Bank (PDB) was established at Brookhaven National Laboratory (BNL) (Bernstein *et al.*, 1977) in 1971 as an archive for biological macromolecular crystal structures (see Chapter 24.1 in the first edition of this volume). It represents one of the earliest community-driven molecular biology data collections. In the beginning, the archive held seven structures, and with each passing year a handful more were deposited. In the 1980s, the number of deposited structures began to increase dramatically. This was due to technological improvements made in all aspects of the crystallographic process, the addition of structures determined by other methods and changes in community views about data sharing. By the early 1990s, many journals required a PDB ID for publication; now virtually all journals require the PDB deposition of not only coordinates, but also experimental data. As of 31 May 2011, the archive contained more than 73 000 structures.

The initial goal of the PDB was to archive structures determined by X-ray crystallography as submitted by the authors. Today, structures are deposited in the PDB that have been determined using X-ray crystallography, nuclear magnetic resonance (NMR) spectroscopy, and, more recently, cryo-electron microscopy (cryoEM). In addition to the structural biologists who deposit data, the international PDB community includes a diverse group of researchers in the biomedical sciences (biologists, chemists, physicists *etc.*), as well as educators and students at all levels. In order to ensure that the PDB remains a single uniform archive freely accessible *via* a collection of ftp tools, the worldwide PDB (wwPDB; http://www.wwpdb.org/) was formed in 2003 (Berman *et al.*, 2003, 2009) with an agreement between three deposition centres: the Research Collaboratory for Structural Bioinformatics (RCSB PDB) in the United States; the Protein Data Bank in Europe (PDBe; previously known as the Macromolecular Structure Database, MSD) at the European Bioinformatics Institute (EBI); and the PDB Japan (PDBj). The BioMagResBank (BMRB) in the United States joined in 2006. In this chapter, we describe the collection, validation, annotation and distribution of data by the wwPDB and provide a brief description of the services provided by the member sites.

24.1.2. Data acquisition and processing

24.1.2.1. Content of the data collected by the wwPDB

The PDB archive consists of entries containing three-dimensional Cartesian coordinates and information specific to the method of structure determination. Related experimental data include structure factors for X-ray experiments and chemical shifts and constraints derived from NMR experiments. NMR depositions in the PDB contain links to the BMRB archive of web-accessible constraints, chemical shifts and other data relevant to NMR structures (Ulrich *et al.*, 1989). In the near future, volumes for electron microscopy will become a part of the PDB archive. Table 24.1.2.1 lists the general information that the wwPDB collects for all structures as well as the information specific to X-ray, NMR and cryoEM experiments.

The definitions of the data items collected are in the PDB Exchange Dictionary (PDBx) (Westbrook, Henrick *et al.*, 2005), which is based on the mmCIF syntax. The mmCIF dictionary contains thousands of terms that define the macromolecular structure and the crystallographic experiment (Fitzgerald *et al.*, 2005). PDBx contains additional terms for NMR and cryoEM. The BMRB-developed NMR-STAR dictionary specifies additional data items linked to NMR structures. These terms were developed in collaboration with the depositors who are experts in these methods. Terms needed for tracking and other information management purposes are also included in PDBx.

24.1.2.2. Data deposition sites

Data are deposited to the PDB *via* one of the wwPDB member sites. Because it is critical that the final archive is kept uniform, the wwPDB works to make sure that the content and format of the final files, as well as the methods used to check them, are the same.

Each deposition to the PDB is represented by a PDB ID – a four character code. The PDB ID is assigned arbitrarily and is an immutable reference to the entry. PDB IDs are never reused and are used as a link between the structure and the literature reference that describes that structure. A unique and immutable integer tag identifies experimental NMR data that are processed and archived at the BMRB. Hyperlinks in the related PDB and BMRB files provide seamless access to all information.

The RCSB PDB (http://deposit.pdb.org/) and PDBj (http://pdbdep.protein.osaka-u.ac.jp/) use the program *ADIT* for data deposition and validation. PDBe processes and annotates data that are submitted *via AutoDep* (http://pdbe.org/deposit) (Tagari *et al.*, 2006). The wwPDB members are developing a single tool that will be used by all sites for deposition and annotation.

BMRB sites at Madison (http://deposit.bmrb.wisc.edu/bmrb-adit/) and Osaka-PDBj (http://nmradit.protein.osaka-u.ac.jp/bmrb-adit/) use *ADIT-NMR* to collect both coordinate and experimental data. NMR experimental data deposited at PDBe are forwarded to BMRB for further processing. NMR experimental data are processed by BMRB and the coordinate data by the other wwPDB sites.

Coordinates and experimental data files from all the sites are sent to the RCSB PDB for inclusion in the archive.

24.1.2.3. Validation and annotation

Validation refers to procedures for assessing the quality of the experimental data, the deposited atomic model and the fit of the model to the data. Annotation refers to the process of adding information to the entry (*e.g.*, cross-references to other biological

Copyright © 2012 International Union of Crystallography

Table 24.1.2.1
Content of data in the PDB

(*a*) *Content of all depositions*
Source – specifications such as genus, species, strain or variant of gene (cloned or synthetic); expression vector and host, or description of method of chemical synthesis
Sequence – full sequence of all macromolecular components
Chemical structure of cofactors and prosthetic groups
Names of all components of the structure
Broad description of the function and/or the composition of the structure
Literature citations for the structure submitted
Three-dimensional coordinates
Keywords and experimental method

(*b*) *Additional items for X-ray structure determinations*
Temperature factors and occupancies assigned to each atom
Crystallization conditions, including pH, temperature, solvents, salts, methods
Crystal data, including the unit-cell dimensions and space group
Presence of noncrystallographic symmetry
Data-collection information describing the methods used to collect the diffraction data including instrument, wavelength, temperature and processing programs
Data-collection statistics including data coverage, redundancy, $R_{\rm merge}$, $\langle I/\sigma(I)\rangle$, data above 1σ, 2σ, 3σ levels and resolution limits
Refinement information including (free) R factor, resolution limits, number of reflections, method of refinement, σ cutoff, geometry r.m.s.d., σ
Structure factors – h, k, l, $F_{\rm obs}$, $\sigma(F_{\rm obs})$, intensity, σ(intensity), flag for free R test

(*c*) *Additional items for NMR structure determinations*
For an ensemble, the model number for each coordinate set that is deposited and an indication whether one should be designated as a representative
Data-collection information describing the types of methods used, instrumentation, magnetic field strength, console, probe head, sample tube
Sample conditions, including solvent, macromolecule concentration ranges, concentration ranges of buffers, salts, antibacterial agents, other components, isotopic composition
Experimental conditions, including temperature, pH, pressure and oxidation state of structure determination, and estimates of uncertainties in these values
Non-covalent heterogeneity of sample, including self-aggregation, partial isotope exchange, conformational heterogeneity resulting in slow chemical exchange
Chemical heterogeneity of the sample (*e.g.*, evidence for deamidation or minor covalent species)
A list of NMR experiments used to determine the structure including those used to determine resonance assignments, NOE/ROE data, dynamical data, scalar coupling constants, and those used to infer hydrogen bonds and bound ligands. The relationship of these experiments to the constraint files are given explicitly
Constraint files used to derive the structure as described in Task Force recommendations
Links (where available) to associated files at BMRB containing chemical shift, filtered constraint and other NMR data

(*d*) *Additional data items for cryo-electron microscopy*
Sample preparation, including aggregation state, concentration, buffer, pH, sample support and description of vitrification procedure
3D reconstruction procedure, including method, nominal and actual pixel size, resolution, contrast-transfer-function correction method, magnification calibration and text description of the reconstruction procedure
3D model fitting procedure, including fitting-procedure type and program used, PDB IDs of models used
3D model refinement, including whether refinement is done in real space or reciprocal space, type of protocol, refinement target criteria
If sample is a 2D or 3D array, symmetry and repeat parameters
If the entry contains a virus, details of the virus host including type, species and growth cell, as well as details of the virus including type, isolate and International Committee on Taxonomy of Viruses ID

data resources). The wwPDB partners have convened three Validation Task Forces (VTFs) to advise them on how best to validate X-ray, NMR and cryoEM structures. Their recommendations will be implemented as part of the joint deposition and annotation system currently under development.

At present, annotation involves the following components:

Covalent bond distances and angles: Proteins are compared against standard geometry values from Engh & Huber (1991); nucleic acid bases are compared against standard values from Clowney *et al.* (1996); sugars and phosphates are compared against standard values from Gelbin *et al.* (1996).

Stereochemical validation: All chiral centres of proteins and nucleic acids are checked for correct stereochemistry.

Atom nomenclature: The nomenclature of all atoms is checked for compliance with IUPAC standards (IUPAC–IUB Joint Commission on Biochemical Nomenclature, 1983; Markley *et al.*, 1998) and adjusted if necessary.

Close contacts: The distances between all atoms within the asymmetric unit of crystal structures and the unique molecule of NMR structures are calculated. For crystal structures, contacts between symmetry-related molecules are checked as well.

Ligand and atom nomenclature: Residue and atom nomenclature are compared against a standard dictionary (http://www.wwpdb.org/ccd.html) for all ligands as well as standard residues and bases. Unrecognized ligand groups are flagged and any discrepancies in known ligands are listed as extra or missing atoms. New ligands are added to the dictionary as they are deposited.

Sequence comparison: The sequence provided by the depositor is compared against the sequence derived from the coordinate records. This information is displayed in a table where any differences or missing residues are annotated. During the annotation process the sequence database references provided by the author are checked for accuracy. If no reference is given, a sequence search against UniProtKB (The UniProt Consortium, 2011) is carried out to find the best match. Any conflict between the depositor's sequence and the sequence derived from the coordinate records is further resolved and annotated by comparison with other sequence databases as needed. Once an entry has been released, the cross-references and mappings to sequence and other databases are maintained and kept up to date in the separate SIFTS resource (http://pdbe.org/sifts), a joint project of PDBe and UniProt.

Distant waters: The distances between all water oxygen atoms and all polar atoms (oxygen and nitrogen) of the macromolecules, ligands and solvent in the asymmetric unit are calculated. Distant solvent atoms are repositioned using crystallographic symmetry such that they fall within the solvation sphere of the macromolecule.

Geometry: The torsion-angle distributions and peptide-bond deviations from *cis* and *trans* conformation are checked. Derived data, such as site records, helix and sheet records for secondary structure, are annotated.

Checks of NMR data by the BMRB: NMR constraints are checked for consistency with the three-dimensional structure and atom nomenclature, chemical shifts are checked for possible referencing errors and outliers.

In almost all cases, serious errors detected by these checks are corrected through annotation and correspondence with the authors.

The wwPDB continuously reviews its annotation methods and will continue to integrate new procedures as they become available and are accepted as community standards.

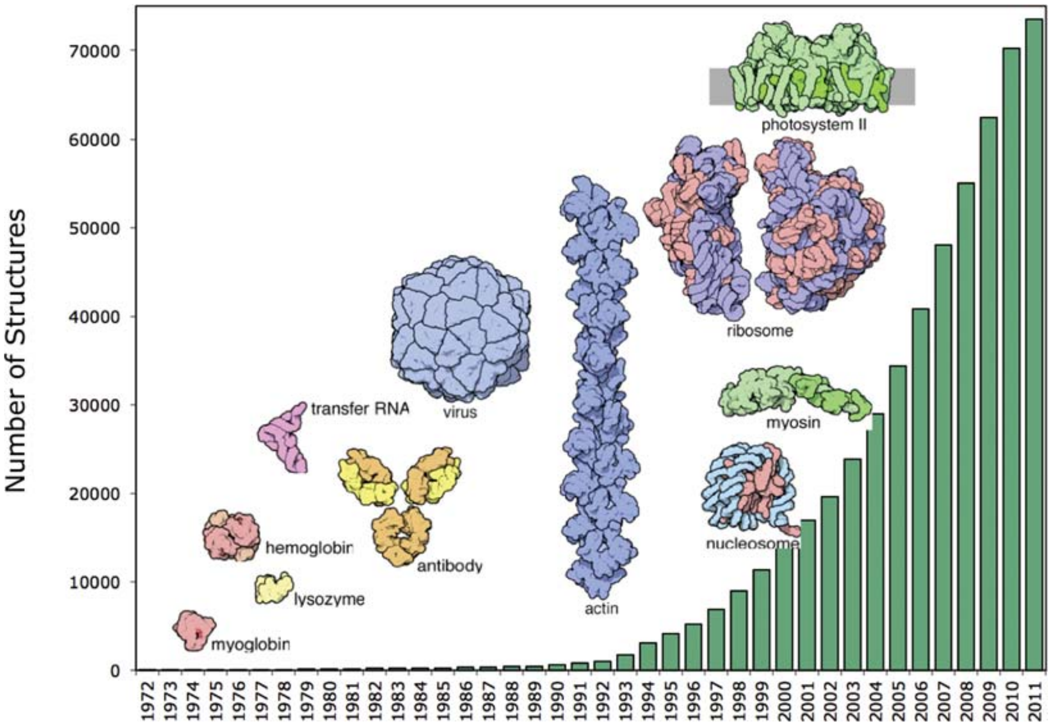

Figure 24.1.2.1
Growth chart of the PDB showing the total number of structures available in the PDB archive per year (as of 31 May 2011) and highlighting example structures from different time periods.

24.1.2.4. Data processing statistics

Fig. 24.1.2.1 shows the growth of PDB data since the archive began, indicating how the complexity of structures released into the archive has increased over time.

As of 31 May 2011, the PDB contains 73 503 publicly accessible structures; of these entries, 64 043 were determined by X-ray methods, 8902 by NMR and 370 by electron microscopy (Fig. 24.1.2.2).

24.1.2.5. Data uniformity

A key goal of the wwPDB is to make the archive as consistent and error-free as possible. Before files are released, all new depositions are reviewed by annotators. Errors found subsequent to release by authors and PDB users are addressed as rapidly as possible and the entries are revised.

The wwPDB member sites collaborate to review all the data in the PDB archive (Henrick *et al.*, 2008; Lawson *et al.*, 2008). In particular, the monomer components and ligands were examined to construct a dictionary that includes the stereochemistry, nomenclature, ideal coordinates, model coordinates, and SMILES and InChI representations. The Chemical Component Dictionary (http://www.wwpdb.org/ccd.html) contains the definitions for all components found in the PDB archive. All instances of these components have been matched against this dictionary and, where necessary, corrections have been made to the PDB files. The sequences, citations and some experimental data items were also corrected. More recently, the archive been reviewed and remediated with the objective of tackling complex problems, including the representation of biological assemblies, residual B factors, peptide inhibitors and antibiotics, and entries in nonstandard crystal frames. Documentation about ongoing remediation efforts is available from http://wwpdb.org.

24.1.3. Data access

24.1.3.1. ftp

The 'PDB archive' is the collection of flat files maintained in three formats (Westbrook & Fitzgerald, 2009) (http://www.wwpdb.org/docs.html): the legacy PDB file format (Bernstein *et al.*, 1977); the PDB exchange format (PDBx) that follows the mmCIF syntax (Fitzgerald *et al.*, 2005, Westbrook, Henrick *et al.*, 2005) (http://mmcif.pdb.org); and the PDBML/XML format (Westbrook, Ito *et al.*, 2005) that is a direct translation of the PDB exchange format. In addition to coordinate data, the archive contains experimental data (structure factors, NMR restraints and chemical shifts). Each wwPDB site distributes the same PDB archive *via* ftp. The archive is updated weekly.

Time-stamped snapshots of the PDB archive are added each year to ftp://snapshots.wwpdb.org. They provide a frozen copy of the archive as it appeared at that time for research and historical purposes. Scripts are available to download all, or part, of a snapshot automatically.

24.1.3.2. Websites

In addition to providing access to the PDB archive, each wwPDB site offers services and resources that provide different views and analyses of the structural data contained within the PDB archive.

24.1.3.2.1. RCSB PDB

The RCSB PDB (http://www.pdb.org) (Berman *et al.*, 2000) provides a website with several functionalities. In addition to downloading files in all formats, a variety of search capabilities are offered. These include searching by PDB ID, author or keyword; searching within a relational database that is populated by the data in the PDBx/PDBML files; or browsing characteristics that have been integrated from external resources (Deshpande *et al.*, 2005). These include biological process, cellular

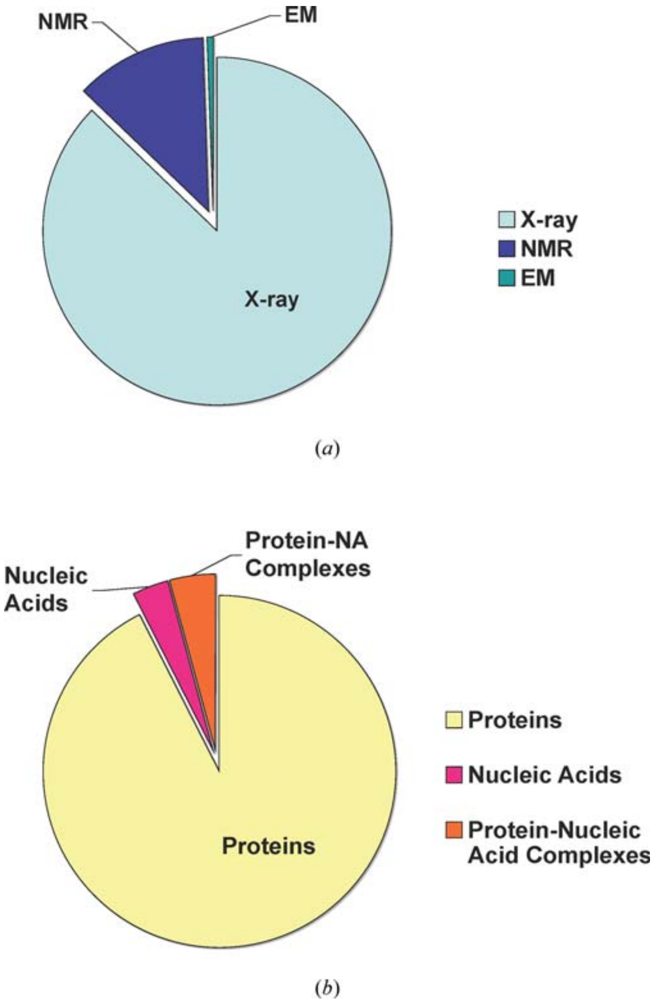

Figure 24.1.2.2
(*a*) Distribution of structures by experimental type (as of 31 May 2011). As of this date, the PDB has 73 503 publicly accessible structures; of these entries, 64 043 were determined by X-ray methods, 8902 by NMR and 370 by electron microscopy. (*b*) Distribution of structures by structure type (as of 31 May 2011). Of the currently available entries, 68 048 are proteins, 2257 are nucleic acids and 3159 are protein/nucleic acid complexes; 39 are other types of molecules.

component and molecular function as defined by gene ontology (The Gene Ontology Consortium, 2000); enzyme classification; medical subject headings (MeSH terms); source organism as defined by the NCBI taxonomy; gene location from Entrez (Wheeler *et al.*, 2006); and folds as classified by SCOP (Murzin *et al.*, 1995) and CATH (Orengo *et al.*, 1997). The structure summary report for each structure is itself searchable. A variety of tabular reports can be made for groups of structures with information about the experiment, the chemistry and biology, and citations. Static pictures and interactive graphics are provided for each structure and protein–ligand interaction from the website. Some of these interactive views use the molecular biology toolkit (*MBT*, http://mbt.sdsc.edu; Moreland *et al.*, 2005). A variety of summary statistics are available as histograms and in tabular form. Advanced searches can be performed on the structure data in combination with the data integrated from over 30 different external sources. Multimedia tutorials are available describing many other features.

A service called MyPDB notifies users *via* email when the PDB releases structures that match customized queries stored at the RCSB PDB site. For application developers, a variety of web services are available to directly access subsets of data and RCSB PDB resources.

Also published at the RCSB PDB site is the *Molecule of the Month*; authored and illustrated by David S. Goodsell, this feature describes a molecule in such a way that non-specialists can learn about the relationship between the structure and function of a particular molecular system.

24.1.3.2.2. PDBj

PDBj (http://www.pdbj.org) maintains a variety of services for querying, displaying and analysing PDB data (Standley *et al.*, 2008). *Structure Navigator* can be used to locate PDB entries that are similar to a query structure or PDB ID. Structural similarity is defined by the newly developed score used in the stand-alone program *ASH* (Alignment of Structural Homologs), which can be run or downloaded from http://www.pdbj.org/ASH/. *ASH* shows high sensitivity and selectivity in recognizing CATH or SCOP domains, without requiring large amounts of CPU (Standley *et al.*, 2004, 2005, 2007). *Sequence Navigator* is a *BLAST* interface to PDBj. The input to *Sequence Navigator* can be a PDB ID or an amino-acid sequence. *GIRAF* (Kinjo & Nakamura, 2009) is an efficient search method for the local atomic alignments of possible ligand binding sites and protein–protein interfaces (http://giraf.pdbj.org). It is not constrained by sequence homology, sequence order or protein fold, and hence is applicable to the cases where no structural homologues can be found to find clues about the possible function of a protein.

Most of the query services described above can be executed as web services using the Simple Object Application Protocol (SOAP), REST or through web browsers. *jV* version 3 (formerly known as *PDBjViewer*) is a molecular-graphics program to display proteins and nucleic acids (Kinoshita & Nakamura, 2004). eProtS, the Encyclopedia of Protein Structures, is an educational resource for learning about biological functions and structural characteristics of protein molecules. eProtS contains explanations for a few hundred protein molecules that are particularly interesting. eProtS is implemented as a Wiki so that motivated structural biologists can contribute articles for the proteins whose structures they have solved. Two derived databases are also available from PDBj. ProMode is a database of normal mode analyses (NMA) of proteins. eF-site (electrostatic surface of Functional site) is a database for molecular surfaces of protein functional sites, displaying the electrostatic potentials and hydrophobic properties together on the Connolly surfaces of the active sites, for analyses of the molecular-recognition mechanisms. eF-seek is a service to search for similar molecular surfaces among known active sites.

24.1.3.2.3. PDBe

PDBe (http://pdbe.org) (Velankar *et al.*, 2010, 2011) aims to bring structure to biology, *i.e.*, to become an integrated resource of structure-related data that provides relevant services, information and tools tailored to the needs of expert and non-expert users alike (Velankar & Kleywegt, 2011). Besides offering basic and advanced search and retrieval systems, PDBe focuses on advanced services, ligand-related resources, integration with other biological data resources, validation and enriched presentation of experimental data. Advanced PDBe services include *PDBeMotif* (http://pdbe.org/motif), a service for analysing detailed molecular interactions and correlating them with sequence or structure patterns (Golovin & Henrick, 2008); *PDBeFold* (http://pdbe.org/fold), a powerful interactive structure-alignment tool (Krissinel & Henrick, 2004); *PDBePISA* (http://pdbe.org/pisa), a quaternary-structure prediction and analysis service (Krissinel & Henrick, 2007); and *PDBeXplore* (http://pdbe.org/browse), a tool that allows browsing and analysis of the structural archive based on familiar chemical and biological classification systems such EC, CATH and Pfam (Velankar & Kleywegt, 2011).

Together with UniProt, PDBe also maintains the SIFTS resource (http://pdbe.org/sifts), which provides entry and residue-level mapping for proteins that are found in PDB entries, as well as cross-reference information to resources such as GO, Pfam, InterPro, CATH and SCOP (Velankar *et al.*, 2005). SIFTS data are used by many of the world's major structural bioinformatics resources (*e.g.*, RCSB PDB, Pfam, UniProt, SCOP) as a source of linking data about structure, sequence and function for PDB entries.

The PDBe website is also a rich source of meta-information about the PDB (statistics, highlights), educational material and Quips (short interactive articles and tutorials about 'quite interesting PDB structures'). PDBe further provides tools that can be included in other websites ('widgets') and that provide up-to-date information. Examples of these are PDBprints (http://pdbe.org/prints) and PDBportfolio (http://pdbe.org/portfolio), which provide key information and images, respectively, about individual PDB entries, and UniPDB (http://pdbe.org/unipdb), which shows the coverage of UniProt sequences by PDB entries. Finally, PDBe provides specialized information and services for the NMR (http://pdbe.org/nmr) and cryoEM (http://pdbe.org/em) communities.

24.1.3.2.4. BMRB

The BMRB (http://www.bmrb.wisc.edu) (Ulrich *et al.*, 1989) collects and disseminates experimental NMR data and joined the wwPDB in 2006 (Markley *et al.*, 2008). The BMRB archive can be searched by database ID, keywords, author, molecule name, sequence, sample conditions or other characteristics. The website contains statistics and resources for the NMR community. BMRB archives data connected with an NMR structure as recommended by the wwPDB NMR Task Force for structural-biology depositions: structural constraints, assigned chemical shifts, and NOESY spectra and/or peak lists. BMRB also supports more comprehensive NMR data depositions by members of the structural-genomics community, which may include additional primary (time-domain) spectra and intermediate results.

The BMRB provides software and tools for validating NMR data and associated structures prior to deposition and tools for visualizing various types of NMR data with or without an associated 3D structure. The BMRB is responsible for processing constraint files and for providing constraints that are consistent with structural models and converted to machine-readable NMR-STAR format to the PDB archive. Filtered restraints, further processed for use by test calculation protocols and longitudinal analyses and validations, are available online (Doreleijers *et al.*, 2005).

24.1.4. Future

Structural biology is a rapidly evolving field that constantly provides new challenges to the collection, curation and distribution of macromolecular structure data. Since 1998, the rate of depositions has tripled and the total holdings have increased by a factor of more than eight. The structures have increased in complexity, with many molecular machines now part of the archive. Data-harvesting tools have made it possible to collect and include more information about each structure. The challenge is to be able to continue to collect data rapidly while maintaining quality and uniformity across the archive.

The maintenance and further development of the PDB archive is a worldwide effort. The willingness of the global community to share ideas, software and data makes it a unique resource for biological research.

The RCSB PDB is supported by the National Science Foundation, the National Institute of General Medical Sciences, the Department of Energy, the National Library of Medicine, the National Cancer Institute, the National Institute of Neurological Disorders and Stroke, and the National Institute of Diabetes and Digestive and Kidney Diseases. Funding for PDBe is provided by EMBL–EBI, the Wellcome Trust, NIH, BBSRC and the European Union. Some earlier developments at PDBe were funded by the MRC and CCP4. PDBj is supported by the Institute for Bioinformatics Research and Development, Japan Science and Technology Agency, and the Ministry of Education, Culture, Sports, Science and Technology. The BMRB is supported by the National Library of Medicine.

Chapter 24.2. The Nucleic Acid Database

B. Schneider, J. de la Cruz, S. Dutta, Z. Feng, L. Chen, J. Westbrook, H. Yang, J. Young, C. Zardecki and H. M. Berman

24.2.1. Introduction

The Nucleic Acid Database (NDB) (Berman *et al.*, 1992) was established in 1991 as a resource for specialists in the field of nucleic acid structure. Over the years, the NDB has developed generalized software for processing, archiving, querying and distributing structural data for nucleic acid-containing structures. The core of the NDB has been its relational database of nucleic acid-containing crystal structures; it also incorporates structures derived by nuclear magnetic resonance spectroscopy (NMR). Recognizing the importance of a standard data representation in building a database, the NDB became an active participant in the mmCIF project (Fitzgerald *et al.*, 2005*a*,*b*) and was the test-bed for this format. With a foundation of well curated data, the NDB created a searchable relational database of primary and derivative data with very rich query and reporting capabilities. This robust database was unique in that it allowed researchers to perform comparative analyses of nucleic acid-containing structures according to the many attributes stored in the database.

In 1992, the NDB assumed responsibility for processing all nucleic acid crystal structures that were deposited into the Protein Data Bank (PDB) (Berman *et al.*, 2003, Bernstein *et al.*, 1977); it was the direct deposit site for nucleic acid structures from 1996 to 1998. In order to meet data-processing requirements, the NDB created the first validation software package for nucleic acids (Westbrook *et al.*, 2003), which is still used today. The NDB continues to provide a high level of information about nucleic acids and serves as a speciality database for its community of researchers. When the NDB began, the world of nucleic acid structures consisted of DNA and RNA oligonucleotides, a few protein–DNA complexes and some tRNA structures. Annotation of structural features was performed manually, and structures were easily classified into a few known molecular architectures by visual inspection. However, in the last several years a whole new universe of nucleic acid structures has emerged. There are many ribozyme structures and many different types of protein–nucleic acid complexes are represented. The additions of ribosomal structures to the archive have increased the number of nucleotide residues resident in the NDB several fold (Moore, 2001) since they emerged in 2000 (Fig. 24.2.1.1).

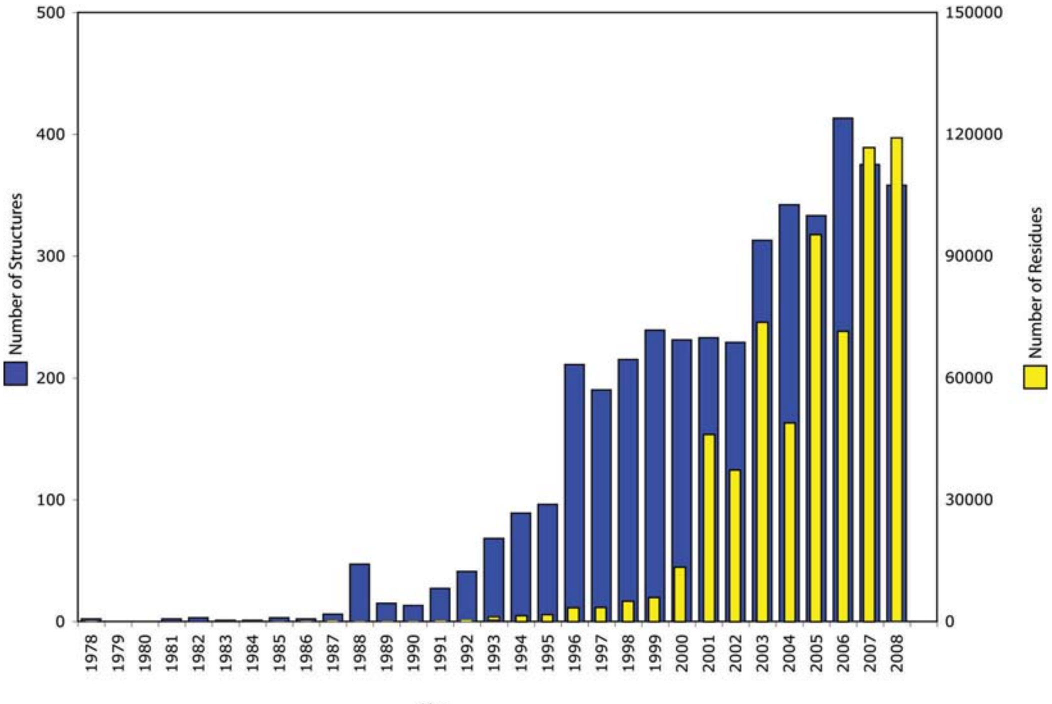

Figure 24.2.1.1
Growth of the NDB. The number of structures available released per year in the NDB is indicated in blue (scale on the left) and the number of nucleotides in these structures in yellow (scale on the right).

24.2.2. Data processing and validation

The NDB created a robust data-processing system to produce high-quality data that are readily loaded into a database. The full capability of this system was demonstrated by the successful processing of ribosomal subunits, which are very large and complex structures.

Early on, the NDB adopted the Macromolecular Crystallographic Information File (mmCIF; Bourne *et al.*, 1997; Fitzgerald *et al.*, 2005*a*,*b*; Westbrook *et al.*, 2005) as its data standard. This format has several advantages from the point of view of building a database: (1) the definitions for the data items are based on a comprehensive dictionary of crystallographic terminology and molecular structure description; (2) it is self-defining; and (3) the syntax contains explicit rules that further define the characteristics of the data items, particularly the relationships between data items (Westbrook & Bourne, 2000). The latter feature is important because it allows for rigorous checking of the data.

The tools first developed by the NDB project are used by the Research Collaboratory for Structural Bioinformatics PDB (Berman *et al.*, 2000) and the Protein Data Bank Japan (both members of the Worldwide PDB, http://www.wwpdb.org/) for processing both proteins and nucleic acids. The validation tool *NUCheck* verifies valence geometry, torsion angles, intermolecular contacts, and the chiral centres of the sugars and phosphates for nucleic acids (Westbrook *et al.*, 2003). Table 24.2.3.1
The information content of the NDB

(*a*) *Identity of depositions, processing information*
Unique codes – NDB, PDB codes
Processing information – deposition, release dates

(*b*) *Primary experimental information stored in the NDB*
Chemical description – the chemical composition of the deposition (content of all chemical constituents of the deposition), detailed description of chemical modifications of the nucleotides
Sequence description – sequences of polymers, nucleic acids and proteins
Structural description – structure type
Citation – authors, title, journal, volume, pages, year

(*c*) *NMR structures*
Coordinate information – atomic coordinates for all models submitted
Experimental data for the deposition – spectrometer, types of NMR experiments, solution content, derivatization

(*d*) *X-ray structures*
Coordinate information – atomic (orthogonal or fractional) coordinates, occupancies and temperature factors for the asymmetric unit
Experimental data for the deposition – cell dimensions; space group for the X-ray structures, spectrometer, solution content *etc.*
Data collection description – radiation source and wavelength; data collection device; temperature; resolution range; total and unique number of reflections
Crystallization description – crystallization method; temperature; pH value; solution composition
Refinement information – program used; number of reflections used for refinement; data cutoff; resolution range; different *R* factors; refinement of temperature factors and occupancies

(*e*) *Derived information stored in the NDB*
Structure summary – descriptor briefly characterizing the structure
Distances – chemical bond lengths; virtual bonds between phosphorus atoms
Angles – valence angles, virtual angles involving phosphorus atoms
Torsion angles – backbone and side-chain torsion angles for nucleic acids and proteins; pseudo-rotational parameters for the sugar rings
Base pairing – detailed description of base pairing, classification by Leontis–Westhof (Leontis & Westhof, 2001) and Saenger (1984) with full identification of all pairs
Base morphology – base-morphology parameters calculated by *3DNA* (Alexandrov & Shindyalov, 2003) using the standard reference frame (Olson *et al.*, 2001)
Special geometrical features – nonbonded contacts, crystal-related geometries (for X-ray structures), symmetry-related coordinates, coordinates for symmetry-related strands, root-mean-square deviations from small-molecule standards for valence geometries
Sequence pattern statistics
Manually annotated structural features – type of helix, classification of double helix, presence of loops, bulges, three/four way junctions
Program-assigned structural features – presence of A/B/Z type of helix, presence of triple, quadruple helices, loops, bulges, three/four way junctions

dictionaries used for checking the structures were developed by the NDB Project from analyses of high-resolution, small-molecule structures (Clowney *et al.*, 1996; Gelbin *et al.*, 1996) from the Cambridge Structural Database (CSD; Allen *et al.*, 1979). The torsion-angle ranges for double-helical DNA forms were derived from an analysis of well resolved nucleic acid structures (Schneider *et al.*, 1997). One important outgrowth of these validation projects was the creation of the force constants and restraints that are now in common use for crystallographic refinement of nucleic acid structures (Parkinson *et al.*, 1996). In addition to geometry checks, the molecular model is checked against the experimental data using *SFCheck* (Vaguine *et al.*, 1999).

Once primary annotation and validation are complete, nucleic acid-specific structural and functional annotations are added. These vary from a broad characterization of nucleic acid conformation as double helical A, B or Z type, to a statement of the presence of a simple structural feature such as a bulge or a helical loop. Proteins from protein/nucleic acid complexes are annotated for their function in the complexes as structural proteins (including, *e.g.*, ribosomal and histone proteins), regulatory (including, *e.g.*, different types of transcription and translation co-factors) and enzymes (polymerases, topoisomerases, endonucleases *etc.*).

24.2.3. The database

24.2.3.1. Information content of the NDB

Structures available in the NDB include RNA and DNA oligonucleotides with two or more bases either alone or complexed with ligands, peptide nucleic acids, natural nucleic acids such as tRNA, and protein–nucleic acid complexes. The archive stores both primary and derived information about the structures (Table 24.2.3.1). The primary data include: the crystallographic coordinate data, structure factors, NMR constraints, and information about the experiments used to determine the structures, such as crystallization information, data collection and refinement statistics. Structural derived information, such as valence geometry, torsion angles and intermolecular contacts, is calculated and stored in the database. Structural and functional features annotated specifically for nucleic acid-containing structures are also loaded to the database.

Some structural features of nucleic acids have historically been derived by different algorithms, and it can be difficult to provide the most reliable values. Whenever possible, the NDB has tried to promote standards that allow structure comparison. An outstanding example of this difficulty was that different programs produced different values for base-morphology parameters (Lavery & Sklenar, 1989; Bansal *et al.*, 1995; Dickerson, 1998; Babcock *et al.*, 1994; Lu *et al.*, 1997). This meant that it was not possible to compare any two structures by using the numbers in the published literature and that it was necessary to recalculate these values for any analysis. To help resolve this problem, the NDB co-sponsored the *Tsukuba Workshop on Nucleic Acid Structure and Interactions* (Tsukuba, Japan, 1999). Key software developers in this field attended and resolved that a single reference frame would be used to calculate these values, and an agreement was reached about the definition of that reference frame (Olson *et al.*, 2001). This work fully quantitated the proposal for base morphology made previously at a meeting in Cambridge (Dickerson *et al.*, 1989). The NDB has recalculated these values for all the structures in the repository using the program *3DNA* (Lu & Olson, 2003), and they are available as output from NDB searches and prepared reports. All the programs have been amended so that they produce very similar values for the base-morphology parameters.

24.2.3.2. User web access

The core of the NDB project is a relational database that can be used to generate queries and reports about the stored structures. This key content of the NDB is supplemented by other services. An integrated web interface (http://ndbserver.rutgers.edu) provides wide and easy distribution of all NDB functionalities. The NDB home page links to the search and Atlas pages, coordinate files, standards for nucleic acid geometry, prepared reports about the database content, and pages with software tools for the calculation and analysis of nucleic acid structural properties.

24.2.3.3. Query capabilities

The NDB relational database has all the data organized into over 90 tables of summary, experimental and derived information, with each table containing five to 20 data items. For instance, the table *citation* contains all items relevant for related literature reference(s), *entity* contains critical items related to chemical entities observed in the structure and *entity_poly* contains the sequences of polymer(s) observed in the structure indexed to the entity table.

A web interface makes the query capabilities of the NDB as widely accessible as possible with a simple *NDB Search* and a more complex *Integrated Search*. The simple *NDB Search* provides a web form to query singular items, or combinations of items, such as NDB and PDB identification codes, author names and year of publication or release, experimental method, as well as chemical and structural characteristics such as the presence of chemical modification, the presence of non-Watson–Crick base pairing, the presence of different types of double helices (B/A/Z/right-handed), or the presence of a tetraplex or a three- or four-way junction. If no selection is made, the entire database is selected. After the query is executed, a list of structure IDs and descriptors that match the desired conditions is returned.

The *Integrated Search* provides the user with a wide range of options for structure selection and the use of Boolean operators to make complex queries. The interface offers pull-down menus to select key components of database entries: citation information, experiment type and details, molecule type (DNA, RNA, protein and ligand) present, presence of nucleic acid modifications, and nucleic acid structural conformation type (description, type and features).

Atlas pages (see below) and several different reports generated on the fly (Table 24.2.3.2) can be used to explore search results.

24.2.3.4. Atlas pages

A powerful reporting option is the NDB Atlas (Fig. 24.2.3.1). An Atlas report summarizes the most important characteristics of a structure with information about the authors, citation, sequence(s) of nucleic acids and proteins reported. Atlas entries contain an outline of the experimental information, a molecular view of the biologically relevant assembly of the reported structure, and links to tables of derived quantities such as torsion angles, base morphology and base pairing. Structural coordinates can be downloaded in PDB and mmCIF formats, and a link is provided to the PDB Structure Explorer page for more details.

Atlas pages are created for all entries directly from the NDB database and are organized by experimental method (X-ray and NMR), and by structure type into broad groups of structures (with possible overlaps) that allow effective browsing of the database. Atlas entries are also linked from database query results.

24.2.4. Distribution of information

In addition to querying and reporting capabilities, the NDB hosts coordinate and experimental data files, database reports, software programs, and other resources. They are available from the web (http://ndbserver.rutgers.edu/) as well as *via* the ftp server (ftp://ndbserver.rutgers.edu). An electronic help desk (ndbadmin@ndbserver.rutgers.edu) provides support.

Table 24.2.3.2
Reports automatically generated for searches of the NDB

Report name	Contains
Descriptor	NDB ID, structure description
NDB and PDB identifiers	NDB and PDB IDs
NDB status	NDB and PDB IDs, descriptor, authors, status, deposition and release dates
Citation information	Authors, title, journal, volume, pages, year
NA sequence	NDB ID, nucleic acid sequence, descriptor
Cell dimensions	Crystallographic cell constants, space group
Refinement data	Resolution limits and reflections used in refinement, *R* factor
Nucleic acid backbone torsion	Backbone torsions with unique residue identifier
Base-pair parameters	Buckle, propeller, opening, shear, stretch, stagger with unique pair identifier
Base-step parameters	Twist, rise, helical rise, tilt, roll, inclination, shift, slide, unique step identifier

24.2.4.1. Structural coordinates and experimental data

Structural coordinate files can be downloaded in mmCIF and PDB formats (Westbrook & Fitzgerald, 2009). Coordinates for the biological assembly of the molecule are provided for X-ray structures. When available, experimental files are made accessible to the community users.

24.2.4.2. Standards and software tools

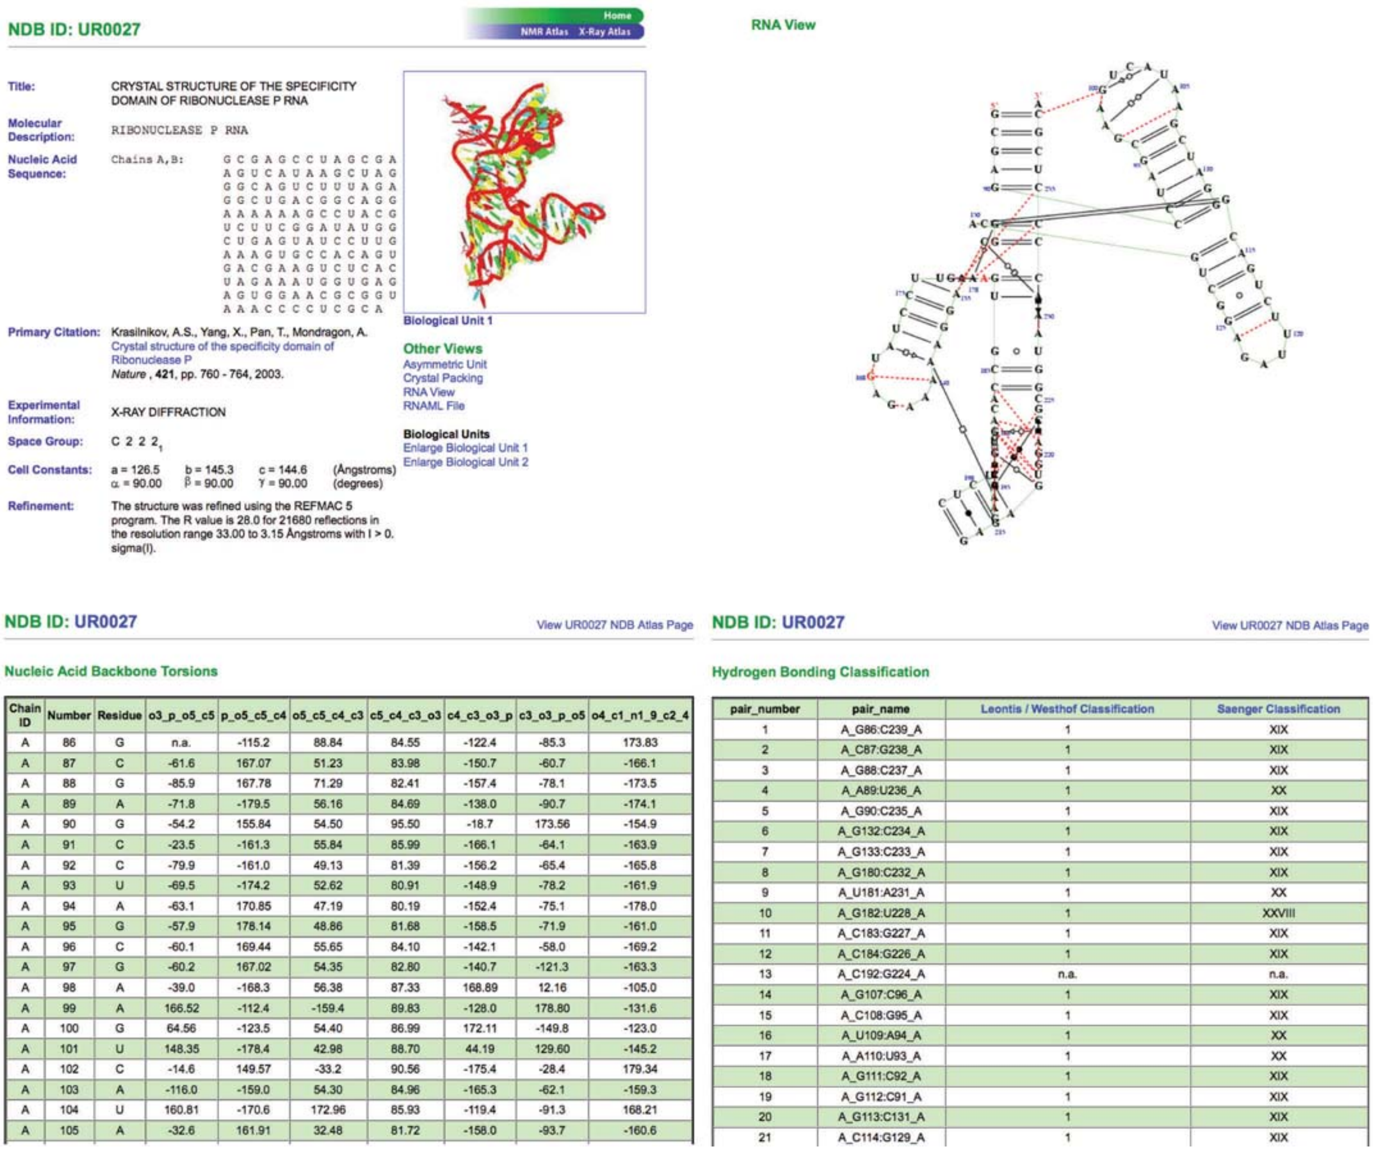
The *Standards* section contains dictionaries of standard (‘ideal’) geometries of nucleic acid components as well as their parameter files for *X-PLOR* (Brünger, 1992). It also provides a full explanation of the standard reference frame (Olson *et al.*, 2001).

The NDB links to several software *Tools*. With the recent increase in the number of RNA structures available, there have been attempts to establish systems for systematic analysis. The result of one of these studies has been the proposal of a classification scheme for the hydrogen bonds in the base pairs (Westhof & Fritsch, 2000; Leontis *et al.*, 2002). The syntax RNAML has also been proposed for representing RNA structural features (http://www-lbit.iro.umontreal.ca/rnaml/). The program *RNAViewer* (Yang *et al.*, 2003) uses Leontis–Westhof classification of base pairs and RNAML syntax to generate two-dimensional (2D) graphical representations of base pairing. *Base Pair Viewer* (*BPView*) visualizes selected base pairs or triplets. In both cases, the base pairs according to the Leontis–Westhof (Leontis & Westhof, 2001) classification are generated on the fly.

Two programs, *predictdnahth* (McLaughlin & Berman, 2003) and *HTHquery* (Ferrer-Costa *et al.*, 2005), analyse the protein DNA-binding helix-turn-helix (HTH) structural motif, and both can be used to determine whether a 3D protein target (from the archive or uploaded by the user) is a DNA-binding protein with the HTH motif.

Several software tools can be downloaded from the NDB site for local installation on the user's computer. *RNAViewer* (Yang *et al.*, 2003) and *S2S* (originally *RNAMLview*; Jossinet & Westhof, 2005) analyse base pairing in a PDB formatted file and draw its 2D representation. Three programs, *3DNA* (Lu & Olson, 2003), *Freehelix98* (Dickerson, 1998) and *hel_param* (Babcock *et al.*, 1993) are provided to compute base-pair parameters.

The NDB Project was funded by the National Science Foundation and the Department of Energy.



NDB ID: UR0027

Title: CRYSTAL STRUCTURE OF THE SPECIFICITY DOMAIN OF RIBONUCLEASE P RNA

Molecular Description: RIBONUCLEASE P RNA

Nucleic Acid Sequence: Chains A,B:

G C G A G C C U A G C G A
A G U C A U A A G C U A G
G G C A G U C U U U A G A
G G C U G A C G G C A G G

Chapter 24.3. The Biological Macromolecule Crystallization Database

D. T. Gallagher and M. Tung

24.3.1. Introduction

The crystallization of a biological macromolecule is a key step in determining its three-dimensional structure by X-ray diffraction. Even for proteins of known structure, it is very difficult to make predictions about crystal-growth conditions or crystal properties. Hence, in crystallizing macromolecules, empirical procedures are used that take advantage of the knowledge gained from past successes. Usually a large set of trials is carried out that varies parameters such as pH, temperature, ionic strength and macromolecule concentration. The number of experiments required for success is variable. In many cases the search ends quickly, either because the right choices were made early or because crystallization occurs over a broad range of conditions. Unfortunately, in other cases, a large number of experiments are required before the discovery of crystallization conditions, and in some cases no crystal conditions are found even after exhaustive searching.

After more than 50 years of experience in the production of diffraction-quality crystals, there is still no generally accepted strategy for searching for the crystal-growth conditions for a biological macromolecule. However, a number of systematic procedures and strategy suggestions have been put forth (*e.g.* McPherson, 1976; Blundell & Johnson, 1976; Carter & Carter, 1979; McPherson, 1982; Gilliland & Davies, 1984; Gilliland *et al.*, 1994, 1996; McPherson, 1999). Most current strategies employ a version of the ‘fast screen’ first popularized by Jancarik & Kim (1991). Fast screens are sets of preformulated solutions similar to those that have frequently produced crystals of other proteins in the past. Crystals are often found quickly in such experiments, but failure results in the need for a more general approach.

The purpose of the Biological Macromolecule Crystallization Database (BMCD) is to provide comprehensive information to facilitate the development of crystallization strategies for the production of crystals suitable for X-ray structural investigations (Gilliland & Davies, 1984). The BMCD includes entries for all classes of biological macromolecules for which diffraction-quality crystals have been obtained, including proteins, nucleic acids and their various complexes.

24.3.2. History of the BMCD

The BMCD has its roots in work that was initiated in Dr David Davies’ laboratory at NIH in the late 1970s and early 1980s (Gilliland & Davies, 1984). While working on a variety of frustrating protein-crystallization problems, a large body of crystallization information was extracted from the literature. This eventually led to a systematic search of the literature and a compilation of data that included almost all of the crystallization reports of biological macromolecules available at the time. In 1983 the data, as an ASCII file, were submitted to the Protein Data Bank (PDB; see Chapter 24.1) for public distribution. The data included the crystallization conditions for 1025 crystal forms of more than 616 biological macromolecules.

In 1987, with assistance from the National Institute of Standards and Technology (NIST) Standard Reference Data Program, the data were incorporated into a searchable database and distributed with software that made it accessible using a personal computer. The database was released to the public in 1989 as the NIST/CARB (Center for Advanced Research in Biotechnology) Biological Macromolecule Crystallization Database, version 1.0 (Gilliland, 1988). In 1990, a second version was released (Gilliland & Bickham, 1990), and in 1994 the BMCD began including data from microgravity crystal-growth studies carried out in orbit (Gilliland *et al.*, 1994). Soon afterwards, the BMCD was migrated to a UNIX platform to facilitate Internet access, and the software was rewritten to enable direct import of data from the PDB. During the period 1997–1998 this reprogramming superceded new data acquisition. Hence, there is a local minimum of crystal entries for that period. In 1999, data acquisition resumed and the size of the BMCD began to increase sharply. In 2008, the BMCD released version 4.01 (Tung & Gallagher, 2009), using the open-source database server PostgreSQL 8.1.3. This version also includes new search features capable of searching for arbitrary text and for ranges of five numeric parameters (pH *etc.*) as described below.

24.3.3. BMCD data

The BMCD stores information in 40 different data types generally divisible into three groups relating to the macromolecule, the crystallization and the crystal itself. Under macromolecule are the name, aliases, biological source genus, tissue *etc.*, mutations, and numbers and sizes of subunit types. The macromolecule sequence is also included but is not yet searchable. The crystal-growth information contains the temperature, the pH, the concentrations of all chemical components including the macromolecule, growth time and the method. Crystal data include the space group, unit-cell parameters, molecules per cell and diffraction resolution. Also included are the V_m and solvent-fraction values. An additional section for each entry records references to published literature.

The BMCD4 (current release, version 4) contains two classes of entries. Those that belonged to BMCD version 3 (about 3500 entries, generally corresponding to information added before 1996) were obtained manually and tend to have complete information relating to crystal growth, including method-specific details. Approximately half of these entries derive from literature reports only and there is no structure in the PDB that directly corresponds to them. These entries have BMCD ID codes that begin with the letter M. The second class of entries are those that are new in version 4, and were obtained by retrieving and parsing data from the PDB roughly covering the period 1997–2007. This represents the new model of data acquisition, utilizing the PDB’s RSYNC download utility to obtain XML files for each entry. The XML files are then processed by custom Java scripts to select data items of interest and convert them into database tables. This conversion involves extensive use of text-parsing scripts and human attention, as described for a similar data-acquisition project by Peat *et al.* (2005). For this processing, filtering and error checking are required in order to correctly interpret unformatted PDB information, especially the crystal conditions.

Copyright © 2012 International Union of Crystallography

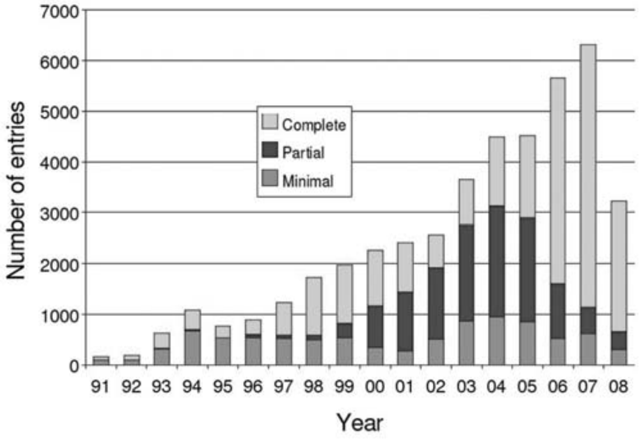

Figure 24.3.3.1
Trends in the completeness of BMCD crystallization conditions.

The resulting entries correspond directly to PDB structures, and the first four characters of the BMCD ID code are the same as the corresponding PDB code. Because the PDB deposition does not require crystal-growth information, many BMCD entries imported from the PDB contain incomplete information. BMCD entries can be divided into three groups according to the completeness of their crystal-growth information: those with 'complete' information, those listing chemicals but not concentrations ('partial'), and those that lack even chemical names but still have some information, such as pH ('minimal'). For a set of 43 698 BMCD entries including the currently available version 4.01 as well as 29 326 entries currently undergoing validation processing, the distribution of these three groups is shown in Fig. 24.3.3.1. As can be seen, most of the entries from 2004 and 2005 are incomplete, but more recently the trend appears to be in favour of recording complete conditions.

An additional complication arises from the wide assortment of synonyms and misspellings in the raw data. Since statistical analysis of chemical conditions requires standardization of chemical names, we are developing methods to interpret and convert both synonyms (*e.g.*, AmSO4, A.S. and AmS for ammonium sulfate) and common misspellings into standard chemical names. This process results in a large reduction in the number of unique chemical names, dominated by a few chemicals that have many synonyms and many misspellings. Efforts to standardize the input and archiving of crystallization information are also underway at major crystallography journals (Einspahr & Guss, 2005).

24.3.4. Web interface

The BMCD is an internet-accessible resource available through the website http://xpdb.nist.gov:8060/BMCD4. The web interface provides a convenient mechanism for browsing through the data contained in the BMCD. The user can examine individual entries, lists of entries selected by customizable search criteria or statistical trends based on the numbers of entries for various properties and parameter ranges. In addition, specific references are listed for most entries.

Two types of search are possible. A simple text search is initiated by input on the home page. For example, a search for 'DTT OR mercaptoethanol' (single quotes are optional in the actual input; the search string is case-insensitive) returns about a thousand entries that contain one or the other (or both) of these reducing agents, while a search for 'dtt mercaptoethanol' has the same result (OR is implicit). A search for "double mutant" returns the 13 entries that contain this phrase, while the search 'double AND mutant' returns a slightly larger superset that includes any entry with both the search terms. The asterisk character functions as a wildcard, enabling the search for "tetra*" to yield a large set that includes tetragonal crystals as well as explicitly tetrameric proteins. Searching for 'mono* NOT monoclinic' retrieves non-monoclinic entries that contain the words monomeric, mononucleotide *etc*. The query syntax is explained on linked information pages.

An advanced search is offered from its own query page, which accepts input in the form of numeric ranges for any of the five parameters: macromolecule concentration, pH, temperature, resolution and year of publication. BMCD entries with parameters that lie within all the specified ranges are then listed as output. In addition, the advanced search accepts text input (like the simple search) to further specify the target set. For example, using the advanced search, one could identify the 14 entries that contain the text string 'adenosine' and have pH between 3 and 6.6, and also have a diffraction resolution between 0.1 and 1.85 Å.

One additional search feature is the ability to request text matches within specific fields. Each entry has distinct text fields for protein name, organism name, space group, chemical names *etc.* (the full list of searchable fields, with examples, is linked to the search page), and these can be searched independently using a colon syntax. For example, the query

```
title: activation
```

will find any entry whose publication title includes the word 'activation'. The query

```
title:″activation domain″
```

will return the smaller set where the title includes this phrase. Multiple field searches may be combined using Boolean operators. A term or phrase not preceded by a field name will be searched through the entire entry (general search). However, field searching and non-field searching cannot be combined in the same query. The way to combine field and general searching is to use the "Content:" field, which is effectively a general search over all fields. Field names are case-specific; all must be completely lower-case, except "Content".

Here are a few examples of correct syntax for field searches:

```
title:″HIV-1 protease″ AND spgrp:P61
title:antibody AND common_name:mouse
title:antibody AND Content:mouse AND NOT
    common_name:mouse
chem_name:aden * AND (author:mckay OR author:steitz)
```

The output of a search begins with the number of entries found, followed by a linked list of their BMCD codes, molecular names and biological sources. The molecular-name field usually includes the scientific name of the molecule along with common synonyms as previously described (Gilliland *et al.*, 1994). By clicking on the ID code of one of the entries all the data pertaining to that entry are displayed.

24.3.5. Reproducing published crystallization procedures

The BMCD contains the information required to reproduce previously reported crystals for a biological macromolecule. Usually, a later batch of macromolecule will not behave identically to previous samples and some optimizing is required, beginning with the reported crystallization conditions. The conditions may be simple to reproduce, but differences in the isolation and purification procedures, reagents, and crystallization methodology of different laboratories can dramatically influence the results. The crystallization conditions in the BMCD should be considered as a good starting point for the search or optimization that may require experiments that vary pH, macromolecule and reagent concentrations, and temperature.

An attempt to reproduce crystals of an isozyme of glutathione *S*-transferase from rat liver (Sesay *et al.*, 1987) is used to illustrate these points. The original crystallization conditions, for the enzyme purified from liver tissue, were archived as entry M0P3. Several years later the same enzyme was cloned and expressed in *Escherichia coli* for further structural studies. The crystals of the original enzyme grew in 3 to 5 days from vapour-diffusion experiments at 4 °C, with droplets containing a protein concentration of 11 mg ml^{-1}, 0.46% β-octylglucoside, 30–37% saturated ammonium sulfate and 0.1 M phosphate buffer pH 6.9 equilibrated against well solutions containing 60–74% ammonium sulfate.

The recombinant enzyme required an optimization of these conditions to produce large single crystals. The recombinant protein crystallized best at the same temperature, with droplets containing a protein concentration of 12 mg ml^{-1}, 0.2% β-octylglucoside, 20–25% saturated ammonium sulfate, 1 mM EDTA and 0.025 M TrisHCl, pH 8.0 equilibrated against well solutions containing 40–50% ammonium sulfate. Both crystallization protocols required the presence of 1 mM (9*R*,10*R*)-9-*S*-glutathionyl-10-hydroxy-9,10-dihydrophenanthrene, a product inhibitor. Thus, in this example, most of the chemical concentrations shifted, and the pH shifted so much that a different buffer was used. Optimized crystals of the recombinant enzyme grew in 5 to 10 days (Ji *et al.*, 1994).

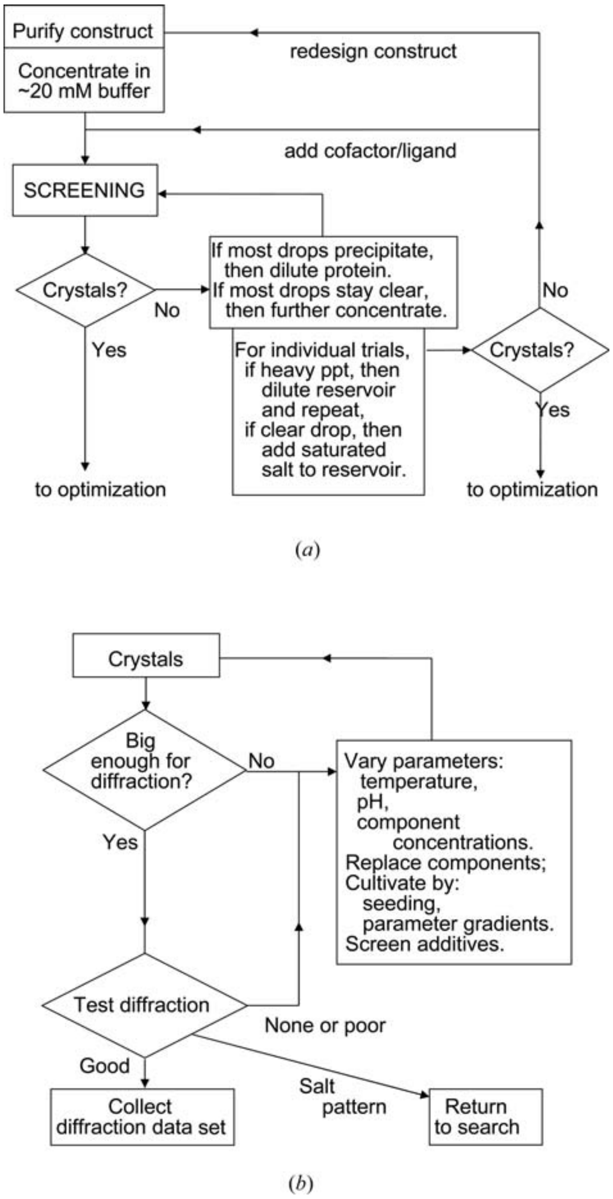
24.3.6. Crystallization screens

A crystallization screen is a set of formulations designed to be mixed with macromolecule solutions as an efficient search for crystallogenic conditions; several are now available commerically as sets of premixed solutions (*e.g.* Cudney *et al.*, 1994). Since the introduction of the fast screen by Jancarik & Kim (1991), almost all attempts to crystallize a new protein begin with a screen of one form or another. Early screens was based on the ideas put forth by Carter & Carter (1979) in their discussion of the use of incomplete factorial experiments to limit the search. The first screens were quite general and applicable to a wide range of biological macromolecules, but screens based on specific classes of molecules such as RNA (Scott *et al.*, 1995) or protein complexes (Radaev *et al.*, 2006) soon developed.

The design of crystal screens is based on previously successful crystallizations. The BMCD has been used extensively for the development of general screens, and can be used to facilitate the development of screens for specific classes of macromolecules. For example, if it were desired to produce a screen for endonucleases, a search of the BMCD would reveal the ranges of key parameters and the most prevalent reagents that have been used to crystallize these enzymes. From an examination of these parameters, a subset of potential crystallization conditions comprising an endonuclease screen could be developed. Another type of focused screen could be one designed to feature a particular crystallant. For example, if L-ornithine were theorized to promote the crystallization of proteins, a screen featuring this additive could be designed by surveying the BMCD for relevant precedents and parameter ranges. Similar methods could be used to focus the initial search for any specific crystallization project.

24.3.7. A general crystallization procedure

The information in the BMCD has been incorporated into general procedures for the crystallization of biological macromolecules not previously crystallized (Gilliland, 1988; Gilliland & Bickham, 1990; Gilliland *et al.*, 1994, 1996). One such general procedure is shown in Fig. 24.3.7.1. Briefly, in this procedure the purified biological macromolecule is concentrated (if possible) to 10 to 25 mg ml^{-1} and dialysed into 10 to 25 mM buffer at a neutral pH or at a pH favouring the solubility of the biopolymer. Other stabilizing agents such as EDTA and/or dithiothreitol may be included at low concentrations to stabilize the biological macromolecule during the crystallization trials. If the biomolecule requires some salt for stability or solubility, then it should be included, but ideally the additional components in the protein solution are kept to a minimum as they limit the search space.



Purify construct
Concentrate in ~20 mM buffer
redesign construct
add cofactor/ligand
SCREENING
Crystals?
No
Yes
to optimization
If most drops precipitate, then dilute protein.
If most drops stay clear, then further concentrate.
For individual trials, if heavy ppt, then dilute reservoir and repeat, if clear drop, then add saturated salt to reservoir.
Crystals?
No
Yes
to optimization
(a)
Crystals
Big enough for diffraction?
No
Yes
Vary parameters: temperature, pH, component concentrations. Replace components; Cultivate by: seeding, parameter gradients. Screen additives.
Test diffraction
None or poor
Good
Salt pattern
Collect diffraction data set
Return to search
(b)

Figure 24.3.7.1
A general crystallization strategy based on the data contained in the BMCD. The overall strategy comprises a search phase (*a*) and an optimization phase (*b*).

Once the macromolecule solution has been prepared, commercial or customized fast screens are carried out using vapour-diffusion experiments. If no crystals appear, it is important to recognize that some trials may contain favourable chemical conditions but fail to produce crystals simply because the concentrations are too high or too low. Thus, each screen trial should be considered not as a single point in composition space but as a vector to be scanned, and any given trial cannot be considered to have failed until its region of transition (between clear drop and precipitation) is observed. If most of the trials produce heavy precipitate, then systematic dilution (either of the reservoirs or of the protein) is advised. If on the other hand most of the drops remain clear, then either more concentrated protein or more dehydrating reservoir conditions will help to bring the protein to its solubility limit in that milieu, and hence to its potential crystal-nucleation point. Individual trials can be manipulated to ensure that no potential crystallization conditions are missed simply because of too high or too low concentation.

Often the first crystals to appear are small, compound or otherwise poor in quality. In this case the optimization phase (Fig. 24.3.7.1*b*) begins by attempting to simplify the crystal conditions (can any components be omitted?), and then systematically varying the crystallization parameters (pH, temperature, chemical concentrations) in the hope of improving size and quality. These experiments generally incorporate controls corresponding to the best crystals obtained so far, so that reproducibility is continually assessed. When crystals are large enough (usually about 0.02 mm), diffraction is tested. Beyond optimizing existing parameters, new components can be substituted (*e.g.*, replacing PEG 4K with PEG 5K MME) or introduced *de novo*, using crystallizations of similar proteins or crystallizations that utilized similar conditions in the BMCD as a guide. Microseeding (often useful to obviate nucleation and to control populations) or macroseeding (to cultivate large, high-quality single crystals) may also be required to optimize crystal growth (McPherson, 1982, 1999).

If the fast screens produce no crystals, a more thorough approach can be undertaken. An analysis of the BMCD data reveals that out of the large number of reagents used as precipitating agents, a small set accounts for the majority of the crystals observed. The pH range for all crystals is quite large, but most proteins crystallize between pH 4.0 and 9.0. Even though temperature can be an important factor, crystallization experiments are usually set up at room (20 °C) or cold-room (5 °C) temperatures. Protein concentration varies quite markedly, but it appears that most experiments use from 5 to 15 mg ml^{-1}. After examining the data in the BMCD, the precipitating agents ammonium sulfate, polyethylene glycol 4000, 2-methyl-2,4-pentanediol and sodium–potassium phosphate might be selected for custom-screening efforts, with initial trials restricted to a pH range of 4.0 to 9.0 and temperatures of 5 and 20 °C. As a prescreening solubility assay, a small amount (2 µl) of the protein is mixed with several concentrations of each of the selected precipitants, and buffered at pH 4.5, 6.0 and 8.0, at both temperatures, monitoring by microscope for precipitation. This establishes the concentration ranges for the reagents for setting up hanging-drop (or any other commonly used technique) experiments. Next, separate sets of experiments that would sample the pH range in steps of 0.5 and reagent concentrations near, at and above those that induce precipitation of the protein would be set up at temperatures of 5 and 20 °C. The assessment of the results of experiments after periodic observations may show (for example by an abrupt precipitation at a particular reagent concentration, pH and/or temperature) a need for finer sampling of any or all of the parameters near the observed discontinuity. In parallel, or if the crystallization trials just described are unsuccessful, another set of experiments can be carried out that include the addition of small quantities of ligands, products, substrate, substrate analogues, monovalent or divalent cations, organic reagents *etc.* to the crystallization mixtures. If this does not prove fruitful, additional reagents may be selected with the aid of the BMCD and new experiments initiated.

24.3.8. The future of the BMCD

Further developments for the BMCD are in progress, with the general goal of increasing its capacity for data analysis, thereby facilitating both scientific understanding and practical applications. It is anticipated that text-parsing and error-correction scripts will soon enable efficient regular import of data from the PDB. This will enable the automatic parsing of all crystallization information into specific chemicals with numerically stored range-searchable concentrations to facilitate detailed statistical analysis. Additionally, future revisions of the database will incorporate taxonomic information on source organisms, classification of proteins, sequence analysis and more powerful searches with more user control of search outputs. The capabilities of the web resource will be expanded to include tools for the development of strategies for new crystallization problems.

The database and its publication are supported by the US National Institute of Standards and Technology. Assistance with database development and support from Gary Gilliland, Jane Ladner and Robert Goldberg is gratefully acknowledged. Certain commercial equipment, instruments and materials are identified in this paper in order to specify the experimental procedure. Such identification does not imply recommendation or endorsement by the National Institute of Standards and Technology, nor does it imply that the materials and equipment identified are necessarily the best available for the purpose.

PART 25. A HISTORICAL PERSPECTIVE

Chapter 25.1. How the structure of lysozyme was actually determined

C. C. F. Blake, R. H. Fenn, L. N. Johnson, D. F. Koenig, G. A. Mair, A. C. T. North, J. W. H. Oldham, D. C. Phillips, R. J. Poljak, V. R. Sarma and C. A. Vernon

25.1.1. Introduction

For protein crystallographers, the year 1960 was the spring of hope. The determination of the three-dimensional structure of sperm-whale myoglobin at 2 Å resolution (Kendrew *et al.*, 1960) had shown that such analyses were possible, and the parallel study of horse haemoglobin at 5.5 Å resolution (Perutz *et al.*, 1960) had shown that even low-resolution studies could, under favourable circumstances, reveal important biological information. All seemed set for a dramatic expansion in protein studies.

At the Royal Institution in London, two of us (CCFB and DCP) had used the laboratory-prototype linear diffractometer (Arndt & Phillips, 1961) to extend the myoglobin measurements to 1.4 Å resolution for use in refinement of the structure (Watson *et al.*, 1963), and we had begun a detailed study of irradiation damage in the myoglobin crystals (Blake & Phillips, 1962). Meanwhile, David Green, an early contributor to the haemoglobin work (Green *et al.*, 1954), and ACTN had initiated a study of β-lactoglobulin (Green *et al.*, 1956) and worked together on oxyhaemoglobin before Green went to the Massachusetts Institute of Technology (MIT) in 1959 on leave for a year. At roughly this time, many of the participants in the myoglobin and haemoglobin work at Cambridge went off to other laboratories to initiate or reinforce other studies. Thus, Dick Dickerson went with Larry Steinrauf to the University of Illinois, Urbana, to start a study of the triclinic crystals of hen egg-white lysozyme.

RJP went to MIT from the Argentine as a post-doctoral fellow in 1958 and worked initially with Martin Buerger. In 1959 he transferred to Alex Rich's laboratory and there he soon came into contact with a number of veterans of the myoglobin and haemoglobin work. In addition to David Green were Howard Dintzis, who had discovered a number of the important heavy-atom derivatives of myoglobin (Bluhm *et al.*, 1958) and was now on the staff at MIT, and David Blow, who had first used multiple isomorphous replacement and anomalous scattering to determine haemoglobin phases (Blow, 1958) and was on leave from Cambridge. The influence of these people, combined with lectures by John Kendrew and then by Max Perutz on visits to MIT, soon convinced RJP that working on the three-dimensional structures of proteins was the most challenging and fruitful research that a crystallographer could undertake. Dintzis, in particular, persuaded him that preparing heavy-atom derivatives was no great problem, and Blow urged him to look for commercially available proteins that were known to crystallize. This soon focused his attention also on hen egg-white lysozyme (Fleming, 1922), but in the tetragonal rather than the triclinic crystal form. He quickly learned to grow crystals by the method described by Alderton *et al.* (1945) and then found that precession photographs of crystals soaked in uranyl nitrate showed intensities that differed significantly from those given by the native crystals. Encouraged by these results, he asked Max Perutz whether he could join the Cambridge Laboratory, but Max, having no room in Cambridge, suggested that he write to Sir Lawrence Bragg about going to the Royal Institution. Bragg replied with an offer of a place to work on β-lactoglobulin with David Green, who had by then returned to London. RJP accepted the offer and left for London late in 1960 – after first discussing what was going on at the Royal Institution with ACTN, who had just arrived at MIT for a year's leave with Alex Rich.

Early in 1961, RJP showed Bragg his precession photographs of potential lysozyme derivatives, and Bragg enthusiastically encouraged him to continue the work, at the same time urging DCP to arrange as much support as possible. This was a characteristic response by Bragg, who was well aware that at least two other groups were already working on lysozyme, Dickerson and Steinrauf at Urbana and Pauling and Corey at Cal Tech (Corey *et al.*, 1952): competition with Pauling was a common feature of his career. In describing his reaction to Bragg's encouragement, RJP recalled Metchnikoff's view of Pasteur. 'He transferred his enthusiasm and energy to his colleagues. He never discouraged anyone by the air of scepticism so common among scientists who had attained the height of their success ... He combined with genius a vibrant soul, a profound goodness of heart.'

25.1.2. Structure analysis at 6 Å resolution

25.1.2.1. *Technical facilities*

In 1961, the Davy Faraday Laboratory was well equipped with X-ray generators. They included both conventional X-ray tubes, operating at 40 kV and 20 mA to produce copper $K\alpha$ radiation, and high-powered rotating-anode tubes that had been built in the laboratory to the design of D. A. G. Broad (patent 1956) under the direction of U. W. Arndt. We had a number of Buerger precession cameras and a Joyce–Loebl scanning densitometer, which had been used in the analysis of myoglobin (Kendrew *et al.*, 1960). In addition, we had a laboratory prototype linear diffractometer (Arndt & Phillips, 1961), which had been made in the laboratory workshop by T. H. Faulkner, and the manually operated three-circle diffractometer that had been used to make some of the measurements in the 6 Å studies of myoglobin (Kendrew *et al.*, 1958) and haemoglobin (Cullis *et al.*, 1961). The diffractometers were used with sealed X-ray tubes, since the rotating anodes were not considered to be reliable or stable enough for this purpose.

At this stage, most of the computations were done by hand, but we did have access to the University of London Ferranti MERCURY computer, usually in the middle of the night. This machine was programmed in MERCURY Autocode. The development of the early computers, their control systems and compilers mentioned in this article have been described by Lavington (1980).

Tetragonal lysozyme crystals with well developed {110} faces (left-hand crystal) and small {110} faces (right-hand crystal).

25.1.2.2. *Lysozyme crystallization*

Tetragonal lysozyme crystals were first reported by Abraham & Robinson (1937) and the standard method of preparation was developed by Alderton *et al.* (1945); RJP used this method. Lyophilized lysozyme was obtained commercially and dissolved in distilled water at concentrations ranging from 50 to 100 mg ml^{-1}. To a volume of the lysozyme solution, an equal volume of 10% (*w*/*v*) NaCl in 0.1 *M* sodium acetate (pH 4.7) was added. About 1 to 2 ml aliquots of this mixture were pipetted into glass vials and tightly capped. Large crystals, frequently with volumes in the range 0.5 to 1 mm^3, grew overnight or during the course of a few days.

The crystals were modified bipyramids with well developed {011} faces and bounded by hexagonal {110} faces that were developed to differing extents in individual crystals (Fig. 25.1.2.1). Many crystals grew in contact with the glass and were less regular in shape. Precession photographs confirmed that the unit-cell dimensions were $a = b = 79.1$ Å and $c = 37.9$ Å, and that the space group was $P4_12_12$ or $P4_32_12$ (Corey *et al.*, 1952). Each unit cell contained eight lysozyme molecules (one per asymmetric unit), molecular weight about 14 600, together with sodium chloride solution that made up about 33.5% of the weight of the crystal (Steinrauf, 1959).

With respect to structure analysis by the method of isomorphous replacement, these two enantiomorphic space groups have the great advantage of exhibiting three independent centrosymmetric projections, on the (001), (010) and (110) planes, corresponding to the *hk*0, *h*0*l* and *hhl* reflections, respectively. As a result, 173 of the 393 reflections from planes with spacings ≥ 6 Å have heavy-atom contributions exactly in or exactly out of phase with the protein contributions to the structure factors. This property greatly facilitated the determination and refinement of heavy-atom positions in the isomorphous derivatives used in the work on lysozyme.

25.1.2.3. *Preparation of heavy-atom derivatives*

For this work by RJP, lysozyme crystals were grown in glass vials in which a 1 ml solution contained between 20 and 50 mg of lysozyme. Attempts were then made to diffuse heavy-atom compounds into the pre-formed crystals. Stoichiometric amounts of heavy-atom compounds, such as K_2PtCl_4, $UO_2(NO_3)_2$, *p*-chloromercuribenzene sulfonate (PCMBS), *p*-chloromercuribenzoate (PCMB) and K_2HgI_4, were added to these vials, and precession photographs were taken of the crystals from each vial. The precession photographs of the putative derivative crystals were compared visually with those from the native protein by superimposing them on a light box. This showed immediately whether the cell dimensions had changed and if there were any significant changes in intensity. If these photographs showed no changes in intensity, then the amount of heavy-atom reagent was increased, and this process was continued until the crystals either showed intensity changes or disintegrated. When intensity changes were detected, the effect of increasing the concentration of heavy atom was explored with the object of establishing the optimum conditions for the preparation of derivatives with high occupancy of a small number of sites. In this way it was sometimes possible to follow decreases and increases of the intensities of weak reflections that went through zero with increasing concentration, and this indicated a reversal of the signs of the reflections from the native and derivative crystals.

In accordance with the example provided by the work on myoglobin, 9° precession photographs, which provide data to a resolution just beyond 6 Å, were used for these trials, and attention was concentrated on the [001] and [100] zones of reflections.

When these exploratory studies had produced a promising derivative, further precession photographs were taken for use in intensity measurements. For this purpose, two Ilford X-ray films were placed one behind the other in the camera cassette and they were exposed for about 24 h to Cu $K\alpha$ radiation from sealed X-ray tubes or for about 4 h to the same radiation from a rotating-anode tube. A second exposure with two films in the cassette was made for about 4 h with the sealed tube or 1 h with the rotating-anode tube in order to cover the full range of intensities that had to be measured. The intensity measurements were performed on the Joyce–Loebl recording densitometer, which scanned each row of reflections automatically but had to be moved manually from row to row. The heights above background of the peaks on the densitometer traces were measured with a ruler and these measurements provided the basic intensity data. Intensities recorded on the two films of each pair were brought to the same scale by calculation and application of a film transmission factor (usually between 2.5 and 3.0) and the corresponding factor relating films exposed for different lengths of time was obtained similarly. Weighted mean intensities were then calculated for each of the reflections. Lorentz–polarization (Lp) factor corrections were derived from a plot of the Lp factor against ($\sin^2\theta/\lambda^2$), without consideration of asymmetric effects (Waser, 1951), and these factors were manually applied to the observed intensities to provide structure-factor measurements on an arbitrary scale.

The structure factors of the heavy-atom derivative crystals, $|F_{HP}|$, were scaled to those of the native protein, $|F_P|$, by a factor K, derived from the equation

$$K^2 \sum |F_{HP}|^2 = \sum |F_P|^2 S,$$

where S was a parameter, between 1.0 and 1.10, that depended on the assumed heavy-atom occupancy and was refined later in the process. Values of $\Delta F = K|F_{HP}| - |F_P|$ were then calculated for use in the determination of the heavy-atom positions.

25.1.2.4. Determination of heavy-atom positions

The high symmetry of the space group was greatly to our advantage, since the heavy-atom positions could be determined from difference-Patterson projection on the (100), (110) and (001) planes. In principle, all three coordinates of a heavy atom can be determined from projections on (100) or (110) alone. In practice, however, it was more straightforward to begin with the interpretation of the simpler projection on (001) before determining the z coordinate of the heavy atom from one of the other projections.

Apart from the effect of cross-over terms, which were sometimes detected as indicated above, these maps are effectively true Patterson maps of the heavy-atom structures of the derivatives. These difference-Patterson maps were calculated on the MERCURY computer and even from time to time by the use of Beevers–Lipson strips – a less demanding task than it might appear, since only about 80 *hk*0 and 60 0*kl* reflections are included within the 6 Å limit.

25.1.2.4.1. The mercuri-iodide (K_2HgI_4) derivative

After trying several levels of substitution, RJP used the K_2HgI_4 salt at a molar concentration eight to ten times that of lysozyme. Based on the fact that lysozyme contains two methionine residues per molecule, and in keeping with a suggestion of Bluhm *et al.* (1958), RJP was expecting to see two heavy-atom sites,[1] but the *hk*0 difference-Patterson map was interpretable in terms of a single site of substitution. This site, however, was very close to the crystallographic twofold axis that runs along a diagonal in the [001] projection of the unit cell, and it proved necessary to correct the details of the first interpretation when phase information became available from other derivatives. It then appeared that there was one HgI_4^{2-} (or HgI_3^-) on the twofold axis between two protein molecules, but that it was best modelled by two closely spaced sites to allow for the elongated shape of the group (see Table 25.1.2.1). Several other heavy-atom salts, including K_2HgBr_4, K_2PtBr_4 and K_2AuCl_4, gave derivatives in which the heavy atom was attached to the same site as K_2HgI_4, and consequently seemed not to provide useful additional phase information.

25.1.2.4.2. The palladium chloride (K_2PdCl_4) derivative

An attempt to use K_2PtCl_4 to produce a useful derivative gave disordered crystals, but a substitute for it was found by soaking crystals in K_2PdCl_4 at a molar ratio of 3:1 relative to lysozyme. Despite the relatively light Pd atom, this derivative gave an easily interpretable difference-Patterson map (see Fig. 25.1.2.2) that yielded very good R factors,

$$R = \textstyle\sum ||F_{HP}| - |F_P|| - |F_H(\text{calc})| / \sum |F_H(\text{calc})|,$$

where the summations are over centric reflections only.

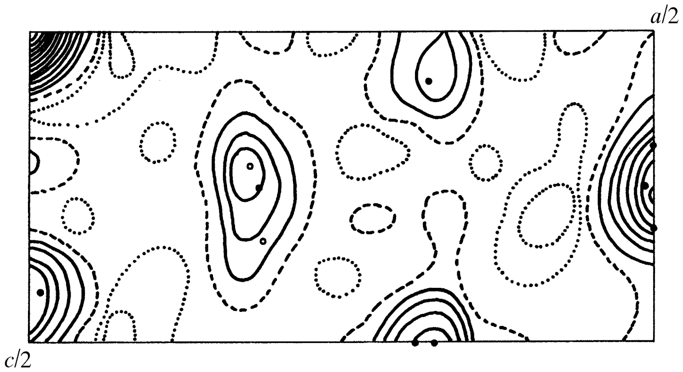

Figure 25.1.2.2
Difference-Patterson *h*0*l* projection map for the derivative obtained with K_2PdCl_4. The ends of heavy-atom double-weight (filled circles) and single-weight (open circles) vectors are shown (R. J. Poljak, unpublished material).

25.1.2.4.3. The o-mercurihydroxytoluene p-sulfonate (MHTS) derivative

The *hk*0 difference-Patterson map of the *p*-mercuribenzene sulfonate (PCMBS) derivative was interpretable in terms of a single site of substitution at 8 Å resolution, but it was not useful beyond about 8 Å because of lack of isomorphism. RJP and RHF then explored the usefulness of MHTS as a derivative. This compound had been specially synthesized by JWHO in the hope that a small rearrangement of groups present in PCMBS would lead to an isomorphous derivative. Happily, this strategy worked, and MHTS gave a useful isomorphous derivative in which the major site overlapped that of PCMBS (Fig. 25.1.2.3).

25.1.2.4.4. Other potential derivatives

As is usual in protein work, RJP tried many other heavy-atom compounds (Poljak, 1963), but none gave useful results. In particular, a uranyl derivative, obtained by the use of UO_2NO_3,

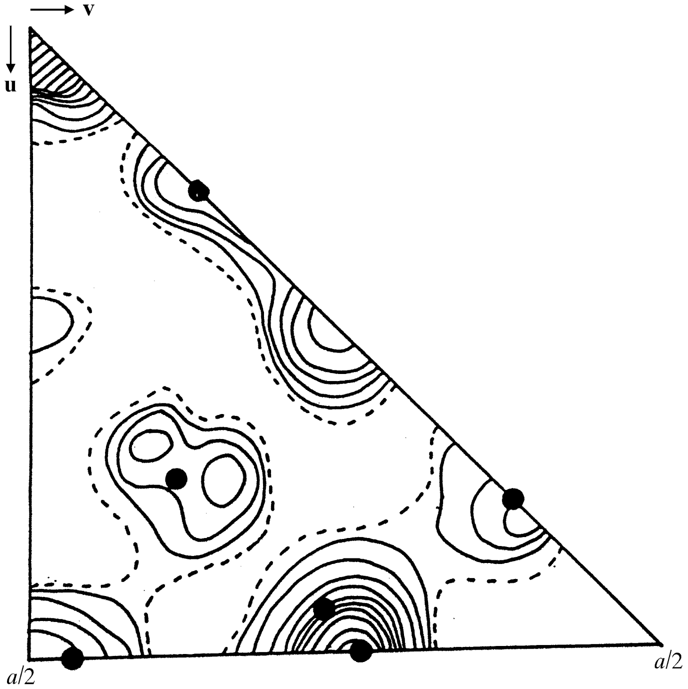

Figure 25.1.2.3
Difference-Patterson *hk*0 projection for the derivative obtained with MHTS. The large peak at $\frac{1}{4}$, $\frac{1}{4}$ is not explained by this solution (Fenn, 1964).

---

[1] In order to study the nature of the ligand formed from K_2HgI_4, RHF and DCP studied the structures of two compounds, $(CH_3)_3S{\cdot}HgI_3$ and $[(CH_3)_3S]_2{\cdot}HgI_4$ (Fenn *et al.*, 1963; Fenn, 1964), which were prepared for this purpose in the laboratory by JWHO. These studies showed that HgI_3 and HgI_4 are, respectively, planar trigonal and tetrahedral in configuration. Meanwhile, Dr Helen Scouloudi was examining the nature of the K_2HgI_4 derivative of seal myoglobin (Scouloudi, 1965) and showed that the ligand was HgI_3^- and not associated with methionine.

gave difference-Patterson maps that were difficult to interpret, and it was not taken further at this stage.

25.1.2.5. Refinement of heavy-atom parameters

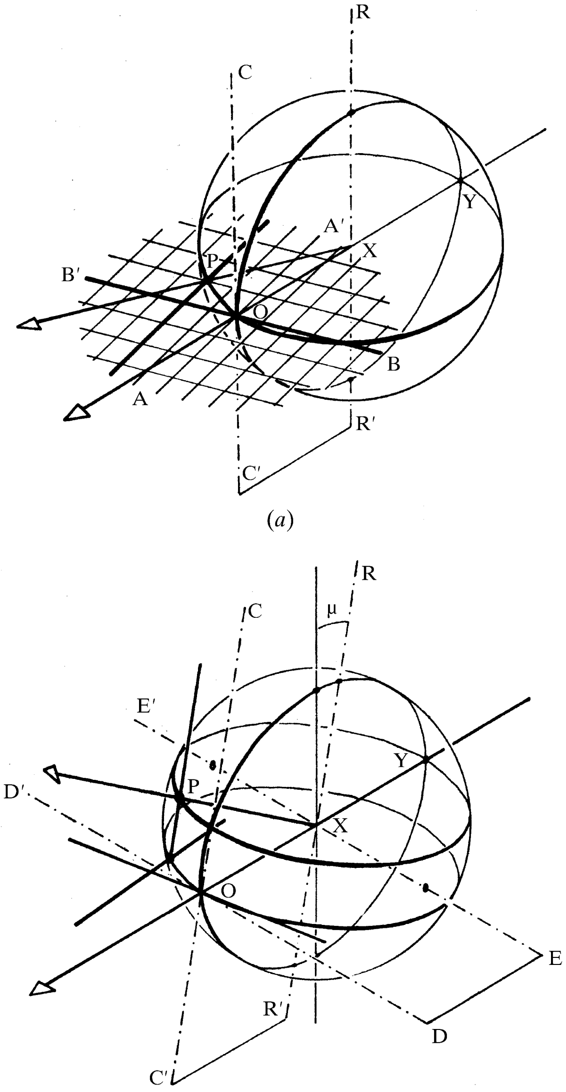
Refinement of the heavy-atom parameters was first performed by the use of Rollett's (1961) least-squares program on the MERCURY computer, using the $|\Delta F|$ values as structure amplitudes. This procedure gave satisfactory results for the K_2HgI_4, K_2PdCl_4 and MHTS derivatives described above, and they were used, therefore, in an attempt to determine the structure of the protein to 6 Å resolution in three dimensions.

25.1.2.6. Analysis in three dimensions

25.1.2.6.1. X-ray intensity measurements

We had three options for the collection of three-dimensional data. First, we could have used precession photographs and densitometry, as in the study of myoglobin (Kendrew *et al.*, 1960). Second, the manually controlled three-circle diffractometer used to make some of the measurements in the 6 Å study of myoglobin (Kendrew *et al.*, 1958) and haemoglobin (Cullis *et al.*, 1962) was available and, third, there was the prototype linear diffractometer (Arndt & Phillips, 1961). We chose the last option, since CCFB, RHF and DCP were well experienced in using the instrument, and it offered the opportunity of measuring the protein reflections automatically and in a relatively short time compared with the other methods. Before he went on leave to MIT, ACTN had written a computer program for the University of London MERCURY computer to process the diffractometer data (North, 1964) and, on his return in September 1961, he readily accepted an invitation to join the team to continue with this and other related aspects of the work.

The design of the linear diffractometer was based directly on the reciprocal-lattice representation of the genesis of X-ray reflections. The principle is illustrated in Figs. 25.1.2.4(*a*) and (*b*), which show the familiar Ewald construction. YXO represents the direction of the incident X-ray beam with X the centre of the Ewald sphere and O the origin of the reciprocal lattice. A′OA, B′OB and C′OC are the principal axes of the reciprocal lattice, here assumed to be orthogonal. XP is the direction of the reflected X-ray beam corresponding to the reciprocal-lattice point P, which lies on the surface of the sphere of reflection. The reciprocal lattice can be rotated about the axis C′OC, and this axis can be inclined to the direction of the incident X-ray beam by rotation about the axis D′OD, which is perpendicular to the incident beam.



(*a*)

(*b*)

Figure 25.1.2.4

Reciprocal-space diagrams showing the direction of the incident X-ray beam, the Ewald sphere and the genesis of a reflection (*a*) in an equatorial plane and (*b*) in the equi-inclination setting. Principal reciprocal-lattice directions are shown as thick lines. They also represent the slides in the diffractometer. The rotation of the diffractometer slide system about the axis C′OC is coupled to the rotation of the crystal about the axis R′XR by gears, pulleys and steel tapes. The counter arm of the diffractometer is represented by the fixed link XP = XO. Reproduced with permission from Arndt & Phillips (1961).

The linear diffractometer was simply a mechanical version of this diagram. The reciprocal lattice was represented by three slides, A, B and C, which were parallel, respectively, to A′OA, B′OB and C′OC. They were mounted to rotate about the axis C′O and arranged so that the saddle P could be set to any position in space within the coordinate system that they defined. This saddle P was connected to the point X by means of a link of fixed length, XP = XO, corresponding to the radius of the sphere of reflection. The link XP always lay along the direction of the reflected X-ray beam and thus became the counter arm of the diffractometer. The crystal was mounted at X for rotation about the axis R′XR (independent of the link XP, which pivoted about an independent coaxial bearing at X). The rotation of the crystal about this axis was coupled by means of gears, pulleys and steel tapes to the rotation of the slide system about the axis C′OC. The axes R′XR and C′OC, held parallel by means of parallel linkages, could be tilted with respect to the incident X-ray beam by rotation about the axes D′OD, E′XE, as shown in Fig. 25.1.2.4(*b*).

The scale of the instrument clearly depended only on the length chosen for XP = XO. In the instruments used in the lysozyme work, this length, which is equivalent to one reciprocal-lattice unit, was five inches. The position of the saddle P on the three slides was controlled by means of lead screws, all of which were cut with 20 turns per inch. Hence the counters, which indicated revolutions and fractions of a revolution of the lead screws, read directly in decimal divisions of reciprocal-lattice units. The screws in slides A and B were driven by means of synchro-receiver motors, forming a synchro link with corresponding transmitters in the control panel. Slide C was set manually, together with the inclination angle μ, for the measurement of upper-level reflections in the Weissenberg equi-inclination mode, Fig. 25.1.2.4(*b*).

The coupling of the rotations of the crystal and reciprocal lattice about the axes R′XR and C′OC, respectively, was interrupted by two ancillary mechanisms. The first simply allowed for independent rotation of the crystal with respect to the slide system and was used for setting the reciprocal-lattice axes in the equatorial plane parallel to slides A and B, and for any fine adjustment of the crystal rotation that might be necessary during the measurement procedure. The second interruption consisted of a mechanism for oscillating the crystal about the position for any reflection while X-ray intensity measurements were made. This oscillation mechanism (Arndt & Phillips, 1961) rotated with the crystal as the diffractometer was being set to a reflection position, and then controlled the independent motion of the crystal for the measurement of the integrated intensity of the reflection. The crystal remained stationary at a given angular setting for time *t*, was rotated at a uniform rate over a predetermined angular range for a time 2*t*, remained stationary at the final angular setting for a further time *t*, and then returned quickly to its original setting. The correct setting for the reflection peak was at the midpoint of the rotation, which might be set to be through any angle from 1 to 5°. For initial adjustments, the motor could be arrested at this midpoint by means of a micro-switch operated by a switching disc rotating with the cam. This disc otherwise actuated contacts that started and stopped the intensity measurements.

The X-ray intensities were measured with a side-window xenon-filled proportional counter made by 20th Century Electronics, together with associated amplifiers and pulse-counting circuits (Arndt & Riley, 1952). The proportional counter had a high quantum efficiency for the measurement of Cu $K\alpha$ radiation (about 80%) and, when the operating potential and pulse-height discriminating circuits were carefully set, it provided useful discrimination against radiation of other wavelengths. The output from the proportional counter and its associated circuitry was fed directly to a teleprinter, which gave both a plain-language print out and a five-hole punched paper tape for input to the computer. Each count was provided with a check digit derived by a 'ring-of-three' circuit, wired in parallel with the main electronic counter. During data processing, the check digit was compared with the count *modulo* 3: inequality of the two numbers was taken to indicate an error in the counting circuit.

Three counts were made: the first was a background count n_1, made while the crystal was stationary on one side of the reflection position; the second was an integrated intensity count N, accumulated as the crystal rotated through the reflection; and the third was a further background count n_2. The background-corrected integrated intensity of the reflection was taken to be

$$N_o = N - (n_1 + n_2).$$

At this stage of the work, measurements were made of one reciprocal-lattice level at a time in the equi-inclination mode that has no blind region at the centre. In each level, the diffractometer was driven to a reflection *hkl* (for example) at the limit of resolution of the data set to be collected. The diffractometer then moved in a series of equal steps along the scanning slide. At the end of each step, the oscillation mechanism took control for the measurement of intensity and background. After each measurement, a further step was taken on the scanning slide, and the process continued until a limit switch, set to the required resolution limit, was reached. The diffractometer then completed the current translation, measured the last reflection in that row, and then moved one step on the stepping slide to the next parallel row. This row was scanned, in the opposite direction, until the limit switch was reached again. In this way, the whole of a reciprocal-lattice level could be measured. In order to change to another level, the vertical slide C and the inclination angle μ had to be manually adjusted.

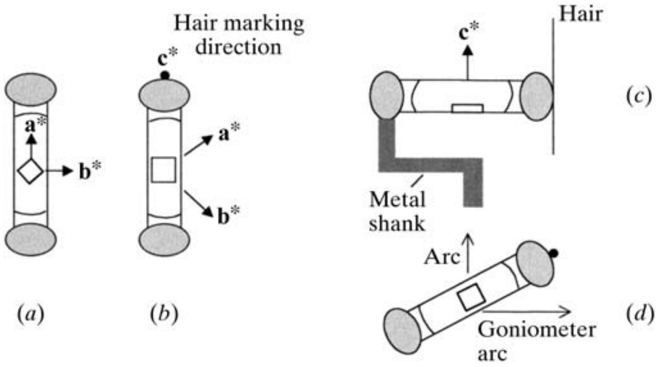


Figure 25.1.2.5
Crystal mounting. (*a*) Rotation about the a^* axis; (*b*) rotation about [110], preliminary to c^* mounting; (*c*) rotation about the c^* axis (elevation); and (*d*) rotation about the c^* axis (plan).

This account ignores two difficulties, one inherent in the design of the diffractometer, and the other specific to the lysozyme crystals. First, the instrument required a good deal of supervision, since it did not set itself very well for the measurement of low-angle reflections. Second, the crystals were not easily mounted so that the *c* axis, the most convenient axis for efficient data collection, since it is perpendicular to the most densely populated reciprocal-lattice planes, coincided with the crystal-rotation axis of the diffractometer.

The first problem was overcome by efficient teamwork and was much eased by the fact that RHF assumed responsibility for the MHTS derivative as part of her PhD work; the second was solved by making most of the measurements from crystals mounted to rotate about the [100] axis. These crystals were oriented so that the b^* and c^* axes were parallel to the horizontal slides of the diffractometer, and the measurements were made in levels of constant *H* by scanning along rows parallel to b^* and stepping to adjacent rows along c^*. A number of reflections could not be measured in this way, however, because reflections near the a^* axis were too broad to measure, particularly in the upper reciprocal-lattice levels. This difficulty was overcome by mounting some crystals with the *c* axis of the tetragonal crystals perpendicular to the length of the capillary tube, with the [110] axis parallel to the tube. These specimens were then mounted on a right-angled yoke so that the capillary tube was perpendicular rather than parallel to the goniometer axis (Fig. 25.1.2.5).

Given the morphology of the crystals, with an essentially square habit bounded by {110} faces (Figs. 25.1.2.1 and 25.1.2.5), all the reflections in the *hkl* octant could be measured in levels with constant *L* values without inclining the capillaries by more than about 40° to the X-ray beam. The horizontal slides of the diffractometer were set to be parallel to the a^* and b^* axes of the crystal. Some quadrants of *hkL* reciprocal-lattice levels were then scanned along rows parallel to the a^* axis and stepped along the b^* axis. Enough measurements were made in this mode to cover the 'blind' region in the *Hkl* levels and provide an appropriate number of intersecting levels for scaling all the measurements into a consistent set.

Care was taken during all these measurements to index the reflections in a right-handed system of axes. Given the transparent relationship between the slide system of the diffractometer and the crystal geometry, this was easily accomplished, and it was necessary for the subsequent use of anomalous scattering (Bijvoet, 1954) in the phase determination.

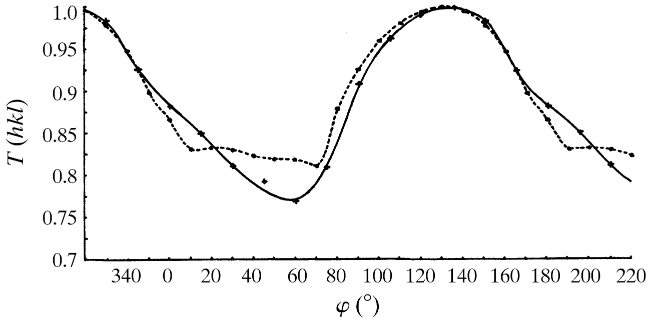

Figure 25.1.2.6
Absorption curve. Variation of relative transmission $T(hkl) = I(\varphi_{hkl})/I_{max}(\varphi)$ [$= 1/A(hkl)$] with rotation angle φ for the 200 reflection and the crystal rotating about the normal to (200). Solid line: measured curve; broken line: calculated curve, neglecting effect of mother liquor and capillary. Reproduced with permission from North *et al.* (1968).

During the measurements from the native and derivative crystals mounted for rotation about [100], the variation in peak intensity of the 200 reflection with φ, the angle of rotation about the axis C′OC (Fig. 25.1.2.4*a*), was also recorded (Fig. 25.1.2.6). (200 is the lowest-order reflection available for this purpose in this space group.) These records were then used in the data-processing stage to correct the measurements for absorption by the method described by Furnas (1957). According to this method, the absorption suffered by the incident and reflected beams for any reflection *hkl* is indicated by the relative intensity of 200 when the X-ray beams are parallel to the reflecting planes *hkl*. This is a fair approximation for reflections at low angles. This method could not be used, however, for the measurements made from crystals mounted to rotate about the [001] axes, since a full rotation about this axis was not possible. These measurements were not corrected for absorption errors.

Finally, the diffractometer was reset manually at regular intervals during data collection to measure the intensities of a number of reference reflections. These measurements were used to monitor the stability of the system and the extent of irradiation damage to the crystal, and they were also recorded on the paper-tape output for analysis by the data-processing program. An attempt was made to minimize irradiation damage by using a shutter to expose the crystal only during the measuring cycle.

25.1.2.6.2. *Data processing*

The measurements N, n_1 and n_2, together with the indices of the reflections, *hkl*, were all printed out in plain language on a teleprinter and punched in paper tape for direct transfer to a computer (Fig. 25.1.2.7). The plain-language record was important during measurement of the low-angle reflections, when the diffractometer had to be adjusted by hand. Not all imperfections in the measurements were easily spotted at this stage, however, and ACTN's data-processing program (North, 1964) therefore incorporated systematic checks on the quality of the measurements.

The program checked for the following contingencies:

(1) malfunction of the diffractometer-output mechanism leading to the paper tape being an inaccurate record of the measurements, generally because the tape punch had failed to perforate the tape or had 'stuttered';
(2) errors by the pulse counters, detected by the 'ring-of-three' circuit;
(3) peak counting rate so high that counting-loss errors were appreciable;
(4) count on reflection not significantly above background;
(5) failure of diffractometer to set crystal or counter correctly; and
(6) gradual drift in the experimental parameters, including movement of the crystal within its mounting and irradiation damage to the crystal.

Figure 25.1.2.8
Format of monitor output in which the computer lists reflections that fail the tests for format or significance. PE1 signifies punching error, indices; PE2, punching error, measurements; PE3, failure of electronic check on counting circuits; SD, standard deviation greater than set limit; N-, net count negative; BG, backgrounds significantly different; N > H, gross counts exceed counting-loss limit. This output was from the version of the program designed to be used with the diffractometer fitted with three counters. The symbols: −, =, + refer, respectively, to reflections measured by the lower, central and upper counters. Reproduced with permission from Arndt *et al.* (1964). Copyright (1964) Institute of Physics.

depended in large part on the fact that the significance of an intensity measurement may be assessed in terms of counting statistics. The standard deviation of a background-corrected count, N_o $(= N - n_1 - n_2)$, is given by $\sigma^2(N_o) = N + n_1 + n_2$, and the ratio $\sigma(N_o)/N_o$ may be taken as an indication of the significance of the measurement. Measurements were rejected when this ratio exceeded unity. N_o might then have been taken as zero but, following Hamilton (1955), we considered it preferable to replace N_o by a fraction (0.33 for centric and 0.5 for acentric reflections) of the minimum background-corrected count that we should have considered acceptable. Reflections were treated in the same way whether the net count N_o was positive or negative, but measurements were rejected if N_o was negative and $|N_o| < \sigma(N_o)$.

Mis-setting of the crystal was frequently revealed by marked inequality of the background counts. Measurements were therefore rejected if the difference between the two backgrounds exceeded three or four standard deviations, that is if $(n_1 - n_2)^2 > b^2(n_1 + n_2)$, where b is the appropriate constant.

After monitoring the quality of the data in this way, the program proceeded: (i) to extract background-corrected counts; (ii) to apply a correction for irradiation damage derived from any systematic variation in the intensities of the reference reflections; (iii) to sort the reflections into a specified sequence of indices; (iv) to apply Lorentz–polarization factors; and (v) to apply absorption corrections (the data for which were read separately from a specially prepared punched tape, Fig. 25.1.2.6). The outputs from this program comprised data sets from a number of individual crystals of the native protein and the three derivatives. The scale factors needed to bring the measurements from the individual crystals of each crystal species to a common scale were determined from the intensities in common rows by the use of a program written by Rollett (Rollett & Sparks, 1960). The scaling factors were applied and the data merged, a weighted-average intensity being determined when more than one estimation was available.

25.1.2.6.3. *The absolute scale of the intensities*

An attempt was made to determine the absolute scale of the measured intensities by comparison with the intensities diffracted by anthracene, a small organic crystal of known structure. This method had worked well in a determination of the absolute scale for seal myoglobin (Scouloudi, 1960), but it did not give a satisfactory result with lysozyme, mainly because of the difficulty of measuring the crystal volumes precisely enough. Accordingly, we used Wilson's (1942) method to provide an estimate of the absolute scale of the intensities, knowing very well that it does not give an accurate estimate for protein data, especially at low resolution. Nevertheless, this scale gave reasonable values for the occupancies of the heavy-atom sites.

25.1.2.6.4. *Re-assessment of heavy-atom derivatives*

Given the three-dimensional data to 6 Å resolution for the native crystals and the three derivatives, it was next possible to calculate three-dimensional difference Patterson maps for the derivatives using the terms

$$|\Delta F|^2 = ||F_{PH}| - |F_P||^2$$

as coefficients in the Fourier series. This synthesis, which is now well known in protein-structure analysis, gives a modified Patterson of the heavy-atom structure in which the heavy-atom vectors appear at reduced weight in a complex background (Blow, 1958; Phillips, 1966). Nevertheless, the $|\Delta F|^2$ maps for $PdCl_4$ and MHTS were readily interpreted in terms of single heavy-atom substitutions, particularly because the vectors involved were all confined to defined Harker sections (Fig. 25.1.2.9).

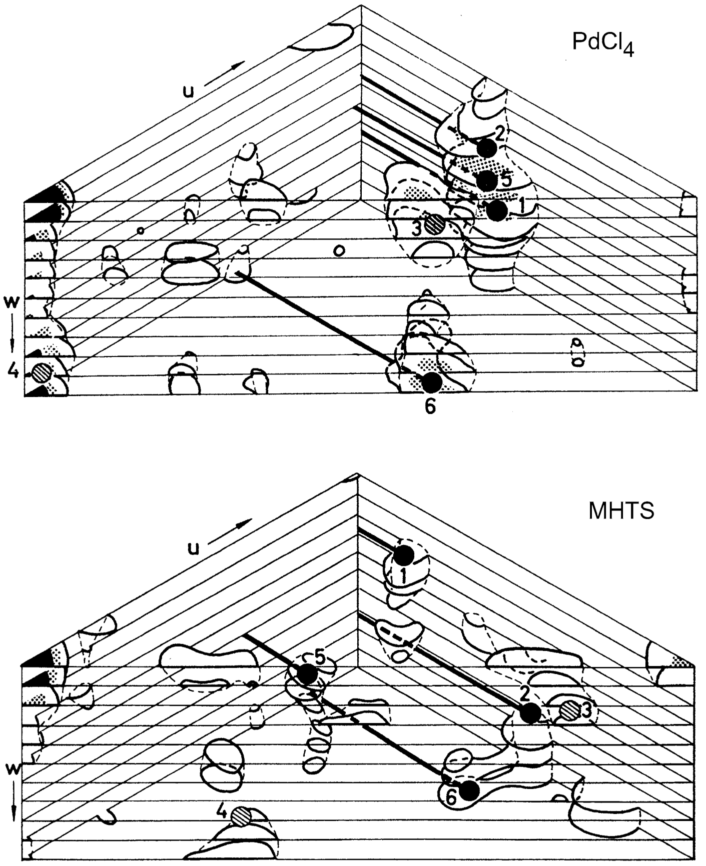

Figure 25.1.2.9
Three-dimensional $|\Delta F|^2$ syntheses for the $PdCl_4$ and MHTS derivatives. The positions of peaks in the Harker sections are marked and numbered (Fenn, 1964).

The map of the HgI_3^- derivative was not so satisfactory, and this led to the discovery, during refinement of the heavy-atom parameters, that the mercury occupancy declined as a function of irradiation time. Consequently, the HgI_3^- data from two individual crystals were treated separately during the remaining stages of the analysis.

The least-squares refinement mentioned in Section 25.1.2.4 was not wholly satisfactory in that it included no provision for refining heavy-atom occupancy. Accordingly, DCP – with some help from ACTN – wrote a computer program for the MERCURY computer based on Hart's (1961) method, in which the heavy-atom positions, occupancies (O) and temperature factors (B) were refined simultaneously together with the scale factors (S) between heavy-atom and native structure factors. All the centric reflections from the [100], [110] and [001] zones were included in this refinement.

The quantity minimized for each derivative was

$$R' = \textstyle\sum(||F_{PH}| - |F_P|| - |F_H|)^2,$$

where F_H is the calculated heavy-atom contribution to the derivative structure factor. The method involves calculating R' for each parameter at its current value p_n and at values $p_n \pm \Delta p_n$ and $p_n \pm 2\Delta p_n$, where each of the parameters is shifted in turn, the shifts having been specified, while the other parameters are at the unshifted value. Thus for each of the parameters (x, y, z, O, B and

† Centric 0, 1, 2*kl* reflections only. ‡ *hk*0 reflections only.

S), four values of R' are obtained for the shifted values plus the value of R' for the unshifted parameters, the latter being denoted ε_u.

Let the minimum value of R' from all the calculations be $\varepsilon_{\min}$ and for the parameter p_n, the minimum of the list of five values of R', be ε_{qn}, corresponding to the value q_n of p_n. Then, according to the method of steepest descents, the shift to be applied to the parameter p_n is

$$(q_n - p_n)(\varepsilon_u - \varepsilon_{qn})/(\varepsilon_u - \varepsilon_{\min}).$$

If $\varepsilon_{qn} = \varepsilon_u$, that is, if the unshifted value of the parameter gave the minimum value of R', then the shift was divided by 4 for the next cycle. Otherwise the shift was kept constant. Thus the new parameters and shifts were determined for the next cycle of refinement, and the process was repeated until convergence.

This program worked well, and RJP, who was reading *Candide* at the time, named it *Pangloss* – it gave the best possible values for the heavy-atom parameters. These values, which include two separate sets for the HgI_3^- derivative, are shown in Table 25.1.2.1. At this stage, an important check was carried out. The coordinates of the heavy-atom site in each derivative were referred to an origin at the junction of a twofold axis and a twofold screw axis. However, there are four such intersections in the unit cell and, in order to ensure that the same origin had been chosen for each derivative, the sign predictions for the centric reflections from each derivative – which were checked by hand throughout this exploratory stage – were compared. They agreed well, thus establishing that the choice of origin was the same for each derivative.

25.1.2.7. Phase determination at 6 Å resolution

These parameters were used to determine the phases of the protein reflections. A proportion of these phases were first determined by the graphical method suggested by Harker (1956), which had been used in the 6 Å stage of sperm-whale myoglobin (Kendrew *et al.*, 1958). We treated the process as a group activity in which different individuals took responsibility for reading out the various Harker components [F_P, F_{PH}, F_H(calc) *etc.*] for each reflection in turn. This was a useful bonding exercise and improved our familiarity with the rather cosmopolitan accents in use within the group. Scientifically, it was also an encouraging experience since it showed that reasonably consistent results could be obtained from the three different derivatives, *and* that the anomalous-scattering measurements were capable of making a significant contribution to the phase determination. It soon became clear that the most significant anomalous contributions had to be included in such a way as to retard the phase of the derivative structure factor if these indications were to agree with the phase predictions derived from the isomorphous differences alone (Fig. 25.1.2.10).

The implication of this observation was that the space group is $P4_32_12$ rather than $P4_12_12$, that is, the fourfold screw axis is left handed.

These results encouraged us to go ahead with the computer calculation of phases by the phase probability method applied to the isomorphous differences (Blow & Crick, 1959; Dickerson *et al.*, 1961) and to the anomalous-scattering differences (Blow & Rossmann, 1961). This program was written by ACTN and it was used first to confirm the space-group identification. Overall, the mean figure of merit obtained with the anomalous contribution consistent with $P4_32_12$ was somewhat higher than the alternative, though to a lesser extent than we had anticipated. This observation led at a later stage to reconsideration of the way in which the anomalous scattering was incorporated in the phase determination (see Section 25.1.3.9).

The quality of the phase determination was indicated by the figure of merit. For the acentric reflections, this was 0.79, an encouraging result since it compared favourably with that obtained in the low-resolution study of haemoglobin (Perutz *et al.*, 1960). The mean figure of merit for the centric reflections, on the other hand, was 0.95, so that the overall value was 0.86. A check on the sign predictions for centric reflections showed that the three derivatives gave satisfyingly similar results.

These phases were also used to calculate difference-Fourier maps, showing the heavy atoms in the derivatives by the use of coefficients

$$|\Delta F| = ||F_{PH}| - |F_P||$$

associated with the protein phases and weighted by the figures of merit of each phase determination. These difference maps in three dimensions are shown in Fig. 25.1.2.11.

They revealed the presence of small subsidiary sites in these two derivatives, but these minor sites were not taken into account.

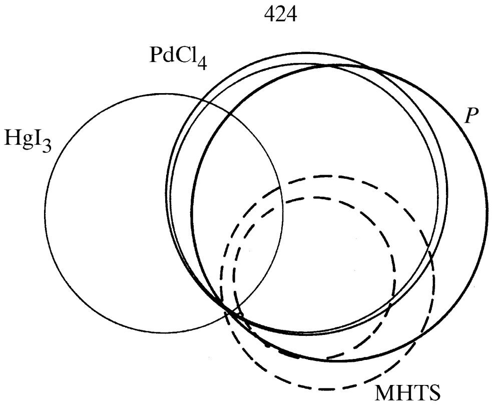

Figure 25.1.2.10

Phase determination for reflection 424. In this Harker diagram, the heavily traced protein circle (with radius $|F_P|$) is labelled P. The circles with radii $|F_{HP}|$ obtained with $PdCl_4$, MHTS and HgI_3 are shown. Values of the anomalous-scattering pairs *hkl* and *khl* were used for $PdCl_4$ and MHTS. The position of the protein vector, weighted by its figure of merit, is shown as a small open circle (R. J. Poljak, unpublished results).

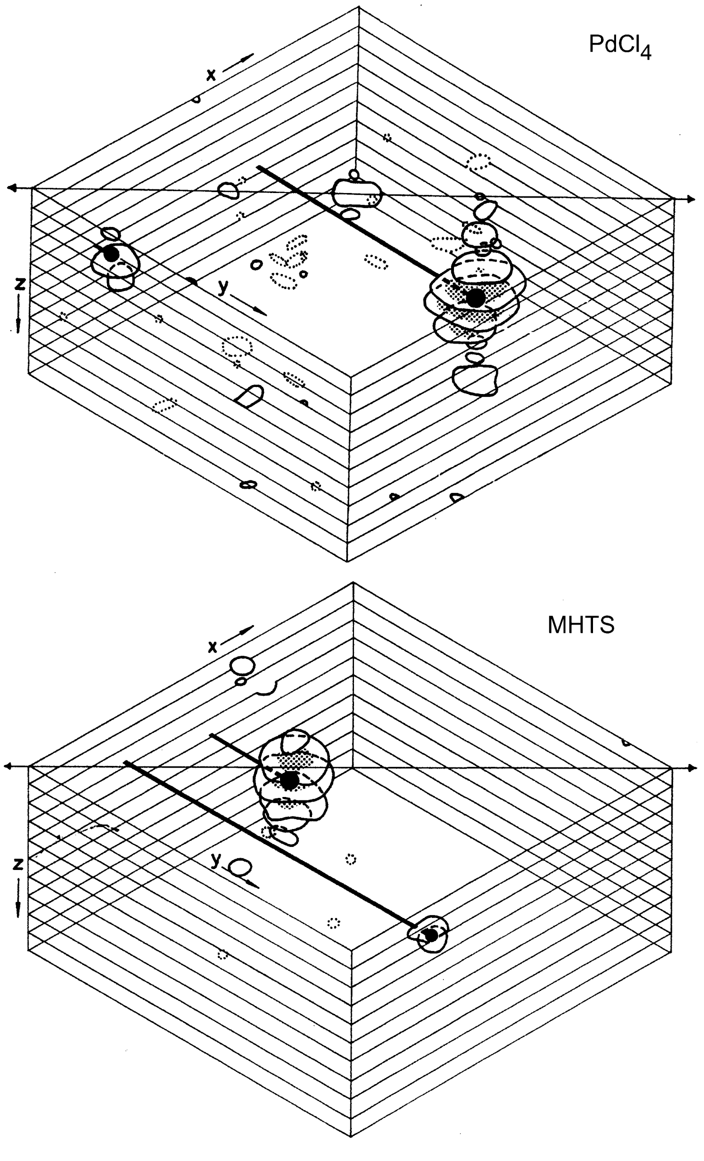

Figure 25.1.2.11
Electron-density difference syntheses showing the main sites of substitution and subsidiary sites with low occupancy in the $PdCl_4$ and MHTS derivatives (Fenn, 1964).

25.1.2.8. *The electron-density map of lysozyme at 6 Å resolution*

The electron-density distribution was calculated on the MERCURY computer, by means of a program written by Owen Mills that was in general use at the time, with structure amplitudes weighted by the figures of merit so as to give the 'best' Fourier (Blow & Crick, 1959). The map was contoured by hand and plotted on clear plastic (Perspex; Plexiglass in the USA) sheets (Fig. 25.1.2.12).

The first objective in studying this map was to determine the boundary of a single molecule. Comparison of the unit cells of various crystal forms of lysozyme (Steinrauf, 1959) suggested that in tetragonal lysozyme, the molecule occupies the full length of the *c* axis and, on average, one-eighth of the *ab* plane. On this basis, the map of Fig. 25.1.2.12 includes the whole of the *c* axis and a sufficient area of each section to ensure that one whole molecule is included in addition to parts of neighbouring molecules. Only contours indicating where the electron density is greater than average are included.

Some featureless regions of average electron density (0.4 e $Å^{-3}$) were immediately apparent. The most marked of these was around the twofold screw axis parallel to **c**. This axis is intersected at intervals of 9.5 Å by twofold rotation axes, and packing considerations, therefore, made it impossible for substantial parts of the molecule to penetrate into the neighbourhood. Similarly, the immediate vicinity of the fourfold screw axis was also without significant features and was clearly a region of intermolecular space. The twofold rotation axes also helped to determine the boundary, particularly where relatively high density approached or intersected them, as it did in two places. It was clear that such regions must represent close contacts or bridges between adjacent molecules.

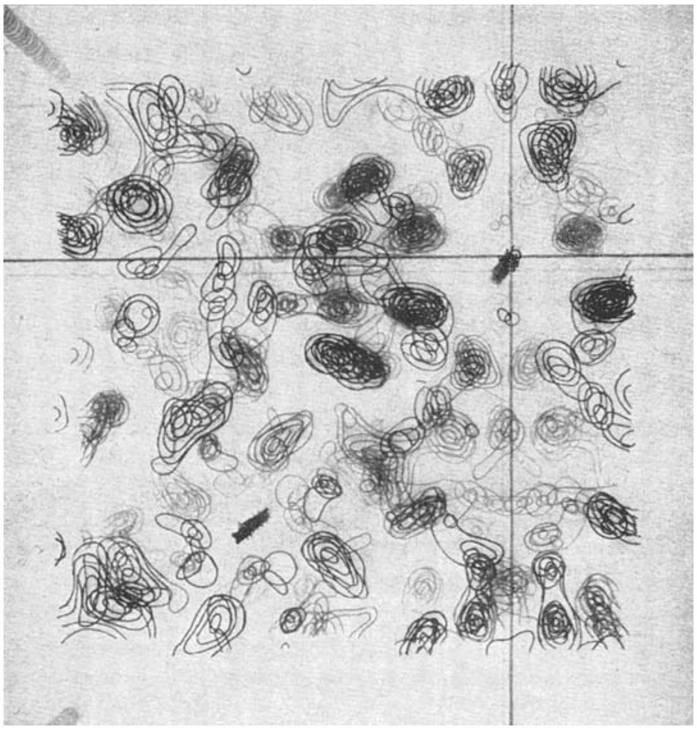

Figure 25.1.2.12
Electron-density distribution in lysozyme at 6 Å resolution viewed parallel to the *c* axis. The horizontal and vertical lines represent the twofold rotation axes and intersect the twofold screw axis, upper right of centre. The fourfold screw axis is at the lower left of centre. The contour interval is 0.07 e $Å^{-3}$, the lowest heavy contour being at 0.6 e $Å^{-3}$. The absolute scale is approximate. Reproduced with permission from *Nature* (Blake *et al.*, 1962). Copyright (1962) Macmillan Magazines Limited.

Following the example of the haemoglobin study (Perutz *et al.*, 1960), we decided at this stage to make a balsa-wood model of the electron density to help visualize the molecule. Instead of producing a stack of sections through the molecule, however, CCFB devised a way of shaping the sections to make a smooth model of the volume occupied by electron density greater than about 0.53 e $Å^{-3}$. The result is shown in Fig. 25.1.2.13.

One asymmetric unit is shown in white, with additional pieces in grey to show alternative shapes. The white pieces together make up the most compact asymmetric unit, which is roughly ellipsoidal in shape with axes 52 × 32 × 26 Å. Later work showed that this asymmetric unit represented a single molecule but, at this stage, we were scrupulous in detailing the alternative interpretations. There is a region of low density that divides the model roughly into two halves, and although we speculated about this we refrained from making any suggestions about its possible significance in our description of the structure (Blake *et al.*, 1962). Instead, we noted that the two halves of the model could be assembled differently, following the crystal symmetry, so as to form a dumb-bell shaped molecule connected at PP′ (Fig. 25.1.2.13*d*).

Our second objective was to determine as far as possible the course of the polypeptide chain and the positions of the disulfide bridges. This proved to be impossible. In comparison with the maps of myoglobin (Kendrew *et al.*, 1958) and haemoglobin (Perutz *et al.*, 1960) at this resolution, it was immediately apparent that this map of lysozyme had a much smaller proportion of clear-cut rod-like features representing α-helices. This was not a surprise, since optical rotatory dispersion measurements (Yang & Doty, 1957) suggested that only 30–40% of the polypeptide chain in lysozyme is in the form of α-helix, as compared with 77% in myoglobin. In addition, Hamaguchi & Imahori (1964) had distinguished the presence of a region of β-sheet in lysozyme before completion of the X-ray analysis. The task of tracing the polypeptide chain, which was difficult with myoglobin, was impossible with lysozyme, since the connectivity of the non-helical regions was often not discernible. The existence of four disulfide bridges, which were expected to have about the same electron density as helices at this resolution, complicated the problem further.

Accordingly, we concluded that defining the shape of the molecule and its tertiary structure would have to await further studies at higher resolution. Meanwhile, Corey and his colleagues (Stanford *et al.*, 1962) and Dickerson *et al.* (1962) published interim accounts of their work at the same time as our work was published (Blake *et al.*, 1962).

At this stage, in the autumn of 1962, RJP left for three months for the MRC Laboratory in Cambridge and then joined Howard Dintzis at Johns Hopkins. At about the same time, DFK joined the team to continue the analysis to high resolution, and LNJ joined DCP as a graduate student and began work related to the activity of the enzyme.

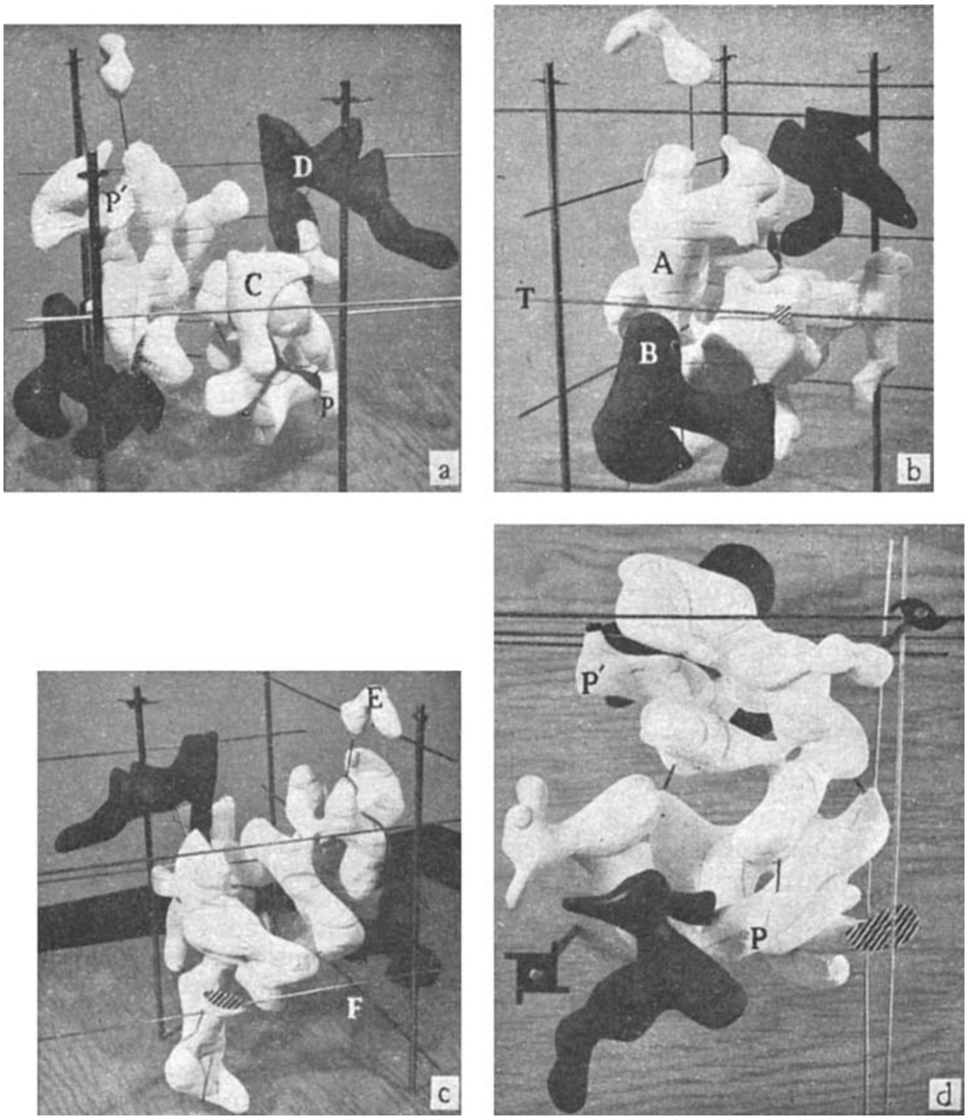

Figure 25.1.2.13
Views of a 6 Å resolution model of the regions in which the electron density exceeds about 0.53 e Å^{-3}. The vertical rods indicate the twofold and fourfold screw axes parallel to **c**. The thinner horizontal rods are twofold rotation axes. At two places, shown hatched, rotation axes pass through continuous regions of density. The white regions alone make up the most compact asymmetric unit of the structure. In part (*b*), the grey section (B) is alternative to the region (A), to which it is related by the twofold axis T. In part (*a*), the grey section (D) is alternative to the white (C), related by the fourfold screw axis. The grey piece (F) in part (*c*) is alternative to the white (E), to which it is related by a unit-cell translation along **c**. The scale is indicated by the framework of symmetry elements, adjacent parallel twofold axes being 18.95 Å apart. Reproduced with permission from *Nature* (Blake *et al.*, 1962). Copyright (1962) Macmillan Magazines Limited.

25.1.3. Analysis of the structure at 2 Å resolution

The structure of chymotrypsinogen (Kraut *et al.*, 1962) at 6 Å resolution was published a few months before the corresponding work on lysozyme. Compared with the work on the globins, however, neither analysis yielded much information on the structures of these proteins, and protein crystallographers generally found them discouraging. Indeed, some went so far as to suggest that only the structures of proteins with a high α-helical content would be amenable to study by X-ray methods. Our reaction, however, as we turned our attention to extending the study of lysozyme to high resolution, was to resolve that each step in the analysis must be conducted as well as possible. We considered carefully, therefore, what improvements might be made to the methods employed hitherto. In particular, we recognized that further work would be needed to identify heavy-atom derivatives suitable for use at high resolution, and we sought improvements in the methods used for data collection, the correction of absorption errors and the use of anomalous scattering in phase determination.

At a purely practical level, one of our major concerns was that our limited access to the London University computer would lead to serious delays in the next stage of the work, which was bound to be even more dependent on computing than the work at 6 Å. Accordingly, we sought support from the Medical Research Council (MRC) for the acquisition of a laboratory-based computer that would be able to handle the computations up to but not including the calculation of a high-resolution electron-density map. Happily, the MRC provided a grant for an Elliott 803B computer, which was installed in the laboratory in March 1963. At the same time, the MRC provided a grant to purchase the commercial version of the linear diffractometer, which was manufactured by Hilger & Watts, Ltd. Since the Elliott 803B had not previously been used for crystallographic computing, this change in our computer involved many members of the laboratory in new programming.

25.1.3.1. Heavy-atom derivatives at 2 Å resolution

The potential usefulness of the three derivatives used at 6 Å resolution for phasing a higher-resolution map was analysed by CCFB and DFK. As the MHTS derivative had much the highest R factor at 6 Å resolution, and the K_2HgI_4 derivative had problems of stability and structure, only the K_2PdCl_4 (PD) derivative seemed likely to be useful for phasing at higher resolutions. An immediate search for additional heavy-atom derivatives was therefore undertaken, which included a re-examination of uranyl nitrate, $UO_2(NO_3)_2$ (UN). Together with other compounds, DFK obtained samples of the then novel $UO_2F_5^{3-}$ ion (UF) from Reuben Leberman at Cambridge, which generated a different pattern of changes in the lysozyme diffraction pattern to any of the previous heavy atoms. When the native phases from the 6 Å map were applied to the UF changes in the centric $hk0$ and $h0l$ zones, they showed a novel two-site binding pattern with a low R factor.

The UF and PD derivatives were examined at 2 Å resolution. Photographs of the centric $hk0$ and $h0l$ zones were taken with a 23° precession angle, the intensities were measured on the Joyce–Loebl densitometer and corrected for Lorentz and polarization effects by a program written by CCFB for the Elliott 803B computer. The heavy-atom parameters obtained in the refinement of these derivatives at 6 Å were used as a starting set for the refinement at higher resolutions. This refinement, like that at 6 Å resolution, was carried out with the program (*Pangloss*) based on Hart's (1961) method, but improved and re-written for the Elliott 803B by DFK.

Initially only the PD and UF derivatives were refined: the mercuri-iodide derivative was not seriously considered to be a potentially useful derivative at high resolution because of the loss of heavy atom with irradiation observed during collection of the 6 Å data. However, it appeared probable that a mean occupancy would be suitable for photographic data, and that the signs predicted by the derivative might be very useful when the other two derivatives gave weak or ambiguous predictions. In fact, the PD and UF derivatives on refinement at 2 Å resolution predicted sets of signs that disagreed to an unacceptable extent, with the PD derivative having a much higher R factor. Refinement of parameters defining the central mercury atom of the mercuri-iodide derivative, followed by calculation of a high-resolution difference-Fourier map using only the most clearly predicted signs, revealed a planar trigonal HgI_3^- ion, whose shape and size were similar to those found by Scouloudi (1965) and Fenn (1964).

Unfortunately, refinement of the mercury and iodine parameters produced a set of protein signs at variance with both previous sets. On the basis of the agreement between F_H(calc) and $F_{PH} - F_P$, both the PD and HgI_3^- derivatives appeared to be non-isomorphous with the native structure. The apparent inability of all three derivatives used at 6 Å to be of use in phasing reflections at higher resolution was disappointing. One possible explanation that was explored for the poor performance of the PD derivative at high resolution, when it showed large changes and a low R factor at 6 Å resolution, was the question of its structure. As with mercuri-iodide, the number of electrons in the halogen substituents exceeded the number in the central palladium atom. Much time was expended in trying to resolve the structure of the square-planar ion without success. This included examining all PdX_4 and PtX_4 complexes, where X is Cl, Br, or I, and calculating double-difference maps between $PdCl_4$ and $PdBr_4$, but without revealing any real indication of structure in the heavy-atom peak.

An extended search for alternative heavy-atom derivatives was therefore begun. Crystals for this purpose were grown as described above (Section 25.1.2.2), except that, on the initiative of DFK, small polyethylene bottles were used instead of glass vials. The polyethylene bottles did not affect crystal size or quality, but allowed crystals to be detached from their surfaces without the damage that occurred when glass vials were used. The search was carried out by the diffusion method. A small number of crystals were isolated together with a known volume of mother liquor, and a solution of the heavy-atom compound, usually at a concentration to make 5 mM in the final solution, was put into a dialysis bag and suspended in the liquid above the crystals. After one or two days, one of the crystals was mounted and an offset 5° screenless precession photograph of the $hk0$ zone was taken. (In these photographs there is no overlap of the zero and first upper levels.) If the approximately 30 unique reflections in this zone showed little or no change in intensities, the crystal was usually not examined further, while those that showed some changes were set aside until a higher-angle precession photograph could be taken. By the use of this technique, a rapid survey of potential derivatives could be made, and those heavy-atom compounds that did not bind to the protein were rapidly dismissed.

Crystals that showed substantial differences in intensity with respect to the native enzyme were used to take $hk0$ and $h0l$ precession photographs. In these studies, the precession angle was reduced to 15° in order to reduce the amount of data to be collected to more manageable proportions, but otherwise the data were collected as for the initial three derivatives. The heavy-atom parameters were also refined in the same way. However, to cope with the disagreements observed between the initial derivatives, a procedure was introduced to combine the refinement of individual derivatives with a refinement of the protein signs in the two centric zones, using all current derivatives together.

When a potential new heavy-atom derivative was identified, the procedure worked as follows. Difference-Fourier maps were calculated, initially at 6 Å and later, when most of the 2 Å signs had been established, at the maximum resolution of the derivative data. When a heavy-atom binding site had been located, its parameters were refined by Hart's method, and the consequences of the refinement, F_P and F_{PH} with their signs and the calculated F_H values, were compared with the corresponding results from other derivatives. The signs of each F_P predicted by the current derivatives were noted, and the most probable sign was determined for each reflection. Initially this was done by inspection, and later by the method of Blow & Crick (1959), with E values provided by the *Pangloss* refinement. The 'best' signs given by this procedure were used to calculate a double-difference map for each derivative with coefficients $[(F_{PH} - F_P) - F_H(\text{calc})]$. When these maps showed either new sites or some new feature at the sites previously included, appropriate alterations were made to the current model of that derivative and further refinement was carried out. If, on the other hand, a derivative showed a high background without interpretable features, it was omitted from further cycles and replaced by another derivative so that a group of four to six derivatives was always in use.

After each derivative had been examined in this way, the set of 'best' signs was updated with the new models of the derivatives, and the procedure was repeated. This procedure worked very efficiently, rapidly indicated a non-isomorphous derivative – or rather one that was significantly less isomorphous than the best – and clearly showed features such as new sites, structure around previously included sites, incorrect or anisotropic temperature factors, and incorrect positional parameters or occupancies. Finally, when the five best derivatives were left in the list, it was immediately apparent, from inspection of the sign predictions in comparison with the E values, which derivatives should be used to phase the high-resolution map.

This method confirmed that MHTS, one of the derivatives used in the 6 Å map but then discarded, was useful at 2 Å resolution and revealed that two new derivatives, UN and UF, were also satisfactory. The poor performance of the MHTS derivative at 6 Å resolution was due to anomalously large changes in the very low resolution reflections, which are sensitive to salt concentrations, but it exhibited good isomorphism at higher resolutions. At about this time, in the summer of 1963, DFK left the laboratory to take up an appointment at Brookhaven National Laboratory.

It became apparent during the course of the heavy-atom search and refinement that the number of suitable derivatives was severely restricted by a feature of the protein. This was the existence of a close pair of very strong binding sites, whose occupation was always accompanied by non-isomorphism. These sites, referred to by the initial derivatives that they bound as the HgI_3^- and PD sites, were found to have a strong affinity for all the complex halogen anions of Pd^{II}, Pt^{II}, Pt^{IV}, Au^{III}, Hg^{II}, Os^{IV}, Ir^{III} and Ir^{IV} that were tried. The sites were mutually exclusive, probably because they shared a protein side chain that acted as one of the important metal-binding groups. The HgI_3 site bound HgI_3^-, $PtCl_4^{2-}$, $PtBr_4^{2-}$, PdI_4^{2-}, $OsCl_6^{2-}$, $IrCl_6^{3-}$ and $AuCl_4^-$. All these compounds caused disordering of the protein structure, as indicated by a decrease in intensities at high resolution, and at least two of the compounds were sensitive to X-irradiation. The PD site also bound $HgCl_2$, $PdBr_4^{2-}$, $PtCl_6^{2-}$, $PtBr_6^{2-}$ and PtI_6^{2-}. All these derivatives were seriously non-isomorphous with the native structure at medium to high resolution, but careful analysis suggested that $PtCl_6^{2-}$ would be useful at low resolution. In contrast, the two uranium compounds, UN [which most probably gave rise to a bound $UO_2(OH)_n$ cation] and UF, gave a substitution pattern entirely different from other derivatives and, in particular, avoided the two sites that gave so much trouble with other complex ions. This finding is in accord with their known tendency to complex with protein oxygens, as opposed to the protein nitrogens that form the binding sites of most other heavy metals.

The two mercury benzene sulfonates that were investigated, MHTS and PCMBS, had a common sulfonate site, but the mercury atoms in the two derivatives were found to be about 3 Å apart. This suggested that they were bound to the protein by their charged sulfonate groups. A similar orientation and position of the benzene ring was implied by the observations that the Hg–SO_3 distance was 5.76 Å in the MHTS derivative, compared with 5.67 Å in the crystal structure of MHTS (Fenn, 1964), and 7.00 Å in the PCMBS derivative, compared with 7.25 Å in the structure of PCMBS. Moreover, the angle Hg(MHTS)–SO_3–Hg(PCMBS) was found in the complexes with lysozyme to be 32°, the same as that calculated from the mercurial structures. This indicates that the benzene sulfonate groups of these two derivatives were fixed in the same position in the lysozyme crystals, and the location of the mercury in the protein crystal depended solely on its position on the benzene ring.

It is interesting to notice that PCMBS, which was investigated first, caused the c axis of lysozyme to lengthen by 1.5% and consequently could not be used at high resolution, while the slightly different MHTS reduced the lengthening to only 0.25% and could be used. This was an early example of an engineered isomorphous derivative. Nevertheless, PCMBS seemed potentially useful at low resolution.

A total of about 50 compounds were used to prepare derivatives (Blake, 1968). Many of these compounds were available commercially but some of the most important, including MHTS and $UO_2F_5^{3-}$, were not. MHTS was designed and synthesised by JWHO, as described above, while the initial sample of $UO_2F_5^{3-}$ was provided by Reuben Leberman, and further supplies were synthesized by CCFB.

In order to prove these new heavy atoms in three dimensions and also to eliminate any 'cyclic' effect due to the use of Fourier methods, 6 Å three-dimensional data were collected early in 1964 for the UF, UN, MHTS, PCMBS and $PtCl_6^{2-}$ derivatives. Two- and three-dimensional Patterson functions were calculated and interpreted afresh. These interpretations were wholly consistent with the results from the high-resolution projections, with the exception of the UN complex. At 3 Å, the $hk0$ and $h0l$ projections showed only two sites, but at 6 Å there appeared to be three additional sites. This point was cleared up when refinement of the 2 Å data collected for phase determination showed that the three extra sites had very high temperature factors, which would result in these peaks being very low at 3 Å resolution. These five compounds were used to phase a second 6 Å electron-density map of the enzyme, as described below, in advance of the analysis at 2 Å, which was based on the only three derivatives that had been found to be reasonably isomorphous at high resolution: MHTS and the two uranyl derivatives, UF and UN.

The discovery of the two uranyl derivatives was not entirely accidental. In the preliminary study at 6 Å resolution, we had been impressed by the potential utility of anomalous scattering in phase determination and had noted the very high value of the imaginary component ($\Delta f'' = 16$) of the anomalous scattering by uranium (Dauben & Templeton, 1955).

25.1.3.2. Intensity measurements

A further advance in diffractometry arose from the observation by DCP that more than one reflection can be measured at the same time in the flat-cone setting of a diffractometer (Phillips, 1964). In the flat-cone setting, the crystal axis is inclined to the X-ray beam as in the equi-inclination setting (Fig. 25.1.2.4*b*), but the motion of the counter is confined to the plane perpendicular to the crystal axis. This flat-cone plane of the reciprocal lattice is midway between the zero-level and equi-inclination levels. When measurements are made in the flat-cone setting from crystals rotating about a reciprocal-lattice axis perpendicular to reciprocal-lattice planes, the crystal and counter settings for reflections in levels adjacent to the flat-cone level are identical to one another and closely similar to those for reflections in the flat cone. This setting is illustrated in Fig. 25.1.3.1.

This property of flat-cone geometry made it possible to modify the linear diffractometer so as to measure three reflections quasi-simultaneously (Arndt *et al.*, 1964). Even more reflections could be measured in this way from crystals with large unit cells but, at

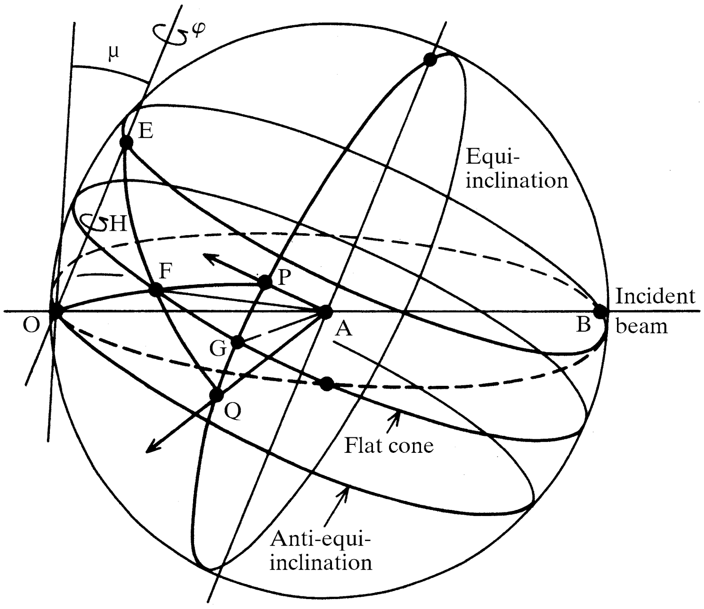

Figure 25.1.3.1

this stage, three 20th Century Electronics side-window proportional counters were mounted in echelon on the counter arm, with appropriate entrance slits and with their windows 0.75 cm apart. The distance of this array from the crystal could be varied between 22 and 50 cm so that the angular separation of adjacent counters lay between 0.034 and 0.015 rad. The separation of reciprocal-lattice levels in which quasi-simultaneous measurements could be made also varied, therefore, from 0.034 to 0.015 reciprocal-lattice units (r.l.u.'s), corresponding to crystal-lattice dimensions of 45 to 100 Å with copper $K\alpha$ radiation.

The array of proportional counters could be set in position on the counter arm by means of horizontal and vertical fine controls. The reflected X-rays passed through adjustable slits before entering the counter windows, and the left and right sides of these slits, or their top and bottom halves, could be blocked to facilitate precise setting.

A disadvantage of using flat-cone as opposed to equi-inclination geometry is that reciprocal-lattice levels measured in a flat cone, and adjacent levels, have a blind region at their centre in which reflections are not accessible. With the linear diffractometer, this blind region falls within the region in which the diffractometer does not automatically set the crystal and counter precisely enough for reliable measurements. The problem is not severe for measurements at low resolution, and it was avoided during the measurement of high-resolution data by the operation of low-angle limit switches that controlled the operation of the scanning and stepping slides. Fortunately, the high symmetry of the lysozyme crystals greatly reduced the seriousness of this problem, since reflections in the blind region close to the rotation axis could usually be measured as symmetry-equivalent reflections in the measurable region.

The first measurements made by this method were 6 Å data for the native protein and the five derivative crystals that had been identified as giving useful phase information at low resolution. Crystals were first mounted to rotate about their *a* axes, and the crystal-to-counter distance was 38.5 cm. Unfortunately, this long crystal-to-counter distance gave rise to weak measured intensities, because of the significant absorption of the reflected X-rays by the air in the counter arm. For this reason we considered filling the counter arm with hydrogen, but came to the conclusion that a simpler approach would be to make the bulk of the measurements from crystals mounted to rotate about their $[\bar{1}10]$ axes.

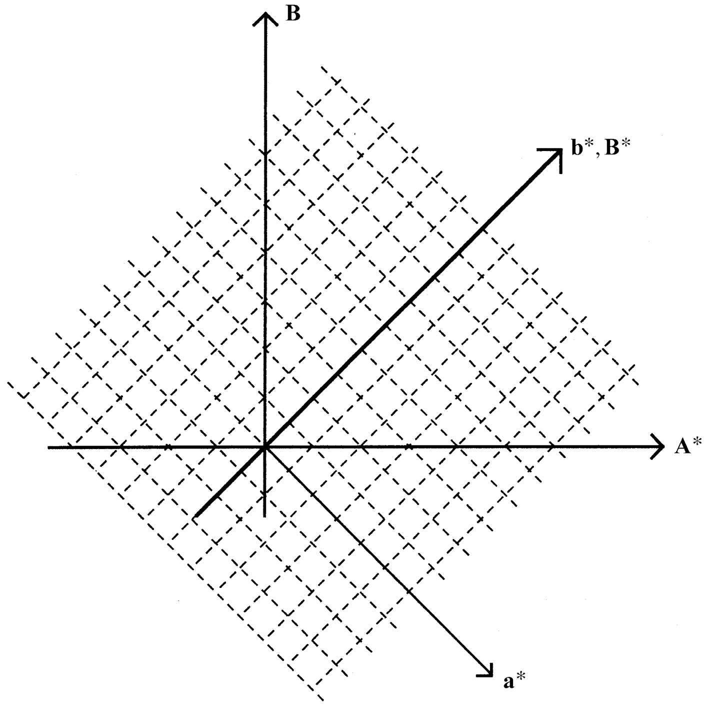

Figure 25.1.3.2
The a^*b^* plane of the reciprocal lattice oriented to rotate about the $[\bar{1}10]$ axis. The indexing of reflections in a monoclinic unit cell with axes A^* and B^* is also shown. A^* coincides with [110] in the tetragonal lattice and B^* coincides with b^*. The rotation axis is the B axis in the monoclinic cell. The reciprocal-lattice dimensions with Cu $K\alpha$ radiation are $a^* = b^* = 0.0195$; $c^* = 0.0406$ r.l.u., while the cell diagonal in the a^*b^* plane is 0.0276 r.l.u.

In this setting, the pyramidal end of the crystals fitted against the wall of the capillary tube in which they were mounted (Fig. 25.1.2.5*b*). The roughly square cross section of the crystals perpendicular to the rotation axis tended to minimize the absorption variation, which was significant with crystals of linear dimensions of about 0.5 mm. The use of large crystals was necessary with a relatively weak X-ray source running at 800 W and with a foreshortened focal spot of 0.4 × 0.4 mm.

It was convenient to index the reflections in a monoclinic cell, as shown in Fig. 25.1.3.2. In this orientation, the reciprocal lattice presented a diamond pattern to the triple-counter array, whose windows were set parallel to the rotation axis. The reflections therefore occurred in two intersecting sets of levels, the odd and even levels, which had to be measured separately. However, the need to collect alternate levels in this way conferred the advantage that the counters could be positioned closer to the crystal (27.1 cm) than in the *a*-axis mounting so that >70% of the reflected X-rays were transmitted to the counters. Despite the complexity that this geometry introduced at the data processing and reduction stages, the significant advantages that it offered at the experimental stage ensured its use. The use of a c^* mounting would have been even more advantageous, but it was ruled out both by the difficulty of mounting the crystals in this orientation and by the fact that the counter arm could not be set to the required length of 18.5 cm.

Native data were collected both from crystals rotated about the *a* axis and from crystals rotated about $[\bar{1}10]$ so that they could be scaled together to form a consistent set of three-dimensional data. For the derivatives, however, data were collected only from crystals rotating about their $[\bar{1}10]$ axes and these data were scaled together to form two sets, one comprising levels with odd indices corresponding to the rotation axis and the other with even indices. These measurements, comprising some 1200 reflections, could be made from a single crystal exposed to the X-ray beam for about 20 h. The odd and even data sets for the derivatives were then scaled separately to the native data to give complete sets of three-dimensional data. These low-resolution measurements were made during the first half of 1964 and, after processing by the methods described below, they were used in September 1964 to calculate a new image of the structure at 6 Å resolution.

25.1.3.3. The second low-resolution map at 6 Å

Our purpose in calculating a new electron-density map at 6 Å was fourfold. First to ascertain whether the procedures used to identify the five derivatives thought to be satisfactory at this level of resolution had worked satisfactorily. Second, to judge the quality of the measurements made by the triple-counter diffractometer. Third, to explore the effects of the modified method of applying absorption corrections to the intensities that are described below, although these were not expected to have a very great effect at low resolution. Fourth, to examine the effectiveness of the new procedure for incorporating anomalous-scattering information in the phase determination, which is also described below.

Comparison of the two sets of structure amplitudes gave a conventional *R* value of 0.075, which is not particularly good – perhaps because of the comparatively large background values associated with these low-angle measurements. However, the mean figure-of-merit obtained in the new phase calculations was 0.97 as compared with the 0.86 obtained originally. The root-mean-square difference in electron density between the two maps was 0.012 e Å^{-3}, from which it may be judged that the two maps were very similar. Nevertheless, the outline of the molecule was certainly clearer in the new map, and within the molecule there was improved continuity, suggesting the course of a folded polypeptide chain, and there were a number of stronger rod-like features suggestive of α-helices. Two of these were prominent, running upwards from right to left, in the view of the new model shown in Fig. 25.1.3.3.

The result was very encouraging, and we therefore went ahead immediately with data collection at 2 Å resolution, using essentially the same methods. At the same time, we began to plan low-resolution studies of inhibitor binding to lysozyme, from which we hoped to derive information about the nature of the enzyme–substrate complex.

25.1.3.4. Intensity measurements at high resolution

At high resolution, measurements were made from only six levels from native crystals set to rotate about the *a* axis while a complete set of data was collected from crystals rotating about $[\bar{1}11]$. As at low resolution, the *a*-axis levels were important for scaling together the odd and even sets of levels measured from crystals rotated about the tetragonal $[\bar{1}11]$ axis. No high-resolution measurements were made from derivative crystals rotated about the *a* axis, the intention being to scale the odd and even subsets of derivative data directly to the native.

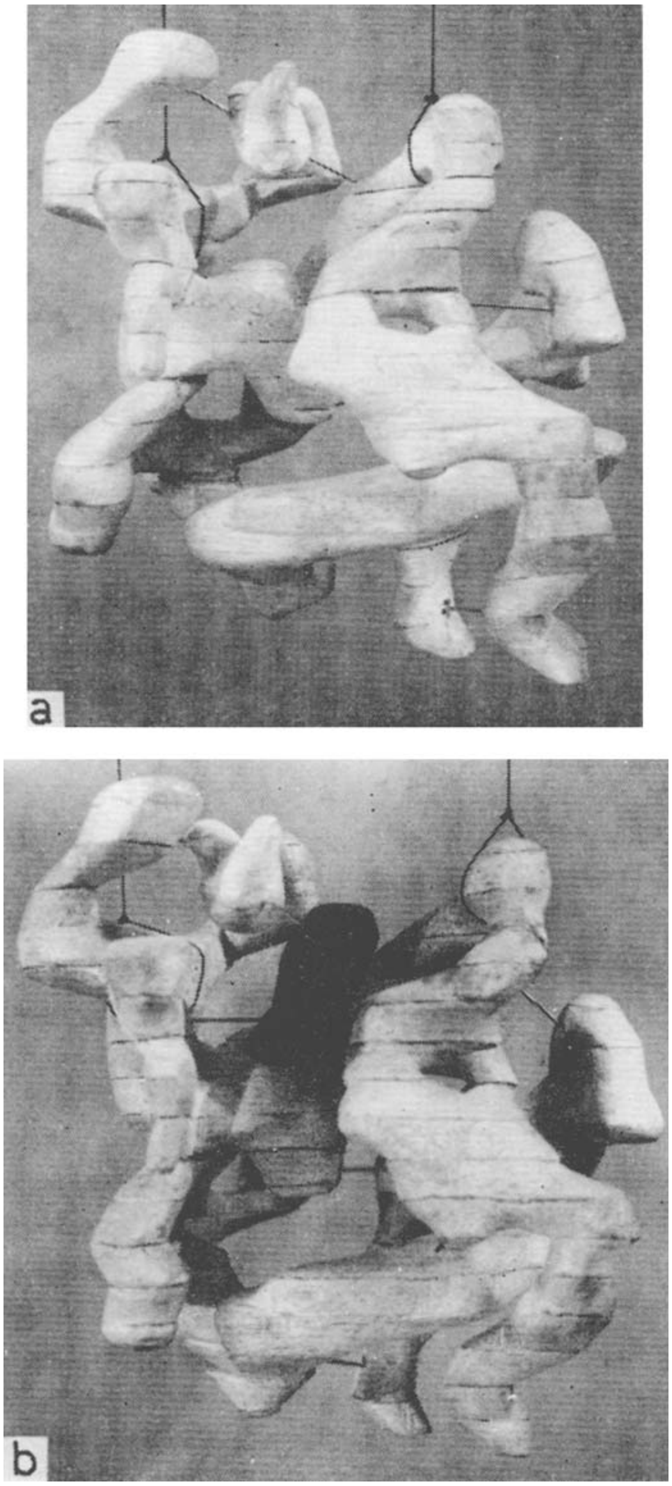

Figure 25.1.3.3
Solid model of the electron density greater than about 0.5 e Å^{-3} in the second study of lysozyme at 6 Å resolution. This view of the model is equivalent to a view of the original model seen horizontally from the right of Fig. 25.1.2.13(*c*). (*a*) The new model has a marked cleft running roughly vertically down the other side of the model, corresponding to the one that can be seen in Fig. 25.1.2.13(*c*). (*b*) The cleft was shown to bind inhibitor molecules. The black density is that observed for the lysozyme–GlcNAc complex at 6 Å resolution.

25.1.3.4.1. Experimental methods

The crystals can be thought of as roughly flattened on $(00\bar{1})$ with liquid between $(00\bar{1})$ and the capillary tube in which they were mounted. In order to minimize the effect of the liquid on absorption, we therefore measured the reciprocal-lattice hemisphere with *C* and c^* positive. Reflections were scanned along *A*, and the origin of the scanning slide was offset for upper levels so that, for example, the centre of the scanning slide was the $H = -4$ for the level $K = 8$.

Crystals could be set fairly well by eye. Viewed through the diffractometer microscope, they looked roughly square in the [001] direction, and the arcs of the goniometer head were set so that the edges were horizontal and vertical. When the crystal was turned through 90° from this position, the reflection of a light held level with the microscope could often be seen in the true (110) face. Setting the crystals on the goniometer head with [001] parallel to one of the arcs facilitated subsequent adjustments.

Fine adjustment of crystal orientation was achieved by setting on the $\bar{4}40$ reflection. For this purpose, C – the vertical slide – was set to 0.1104 and the inclination angle to $\mu = 3° \, 5'$. Then, if one arc was set fairly well by eye, the other could be oriented parallel to the incident X-ray beam and adjusted to locate the reflection. The two arcs were then adjusted in turn to give the optimum setting, in which the crystal was rotated about the normal to the ($\bar{4}40$) plane.

The orientation in the AC reciprocal-lattice plane was determined by returning the vertical slide to zero and setting the upper (scanning) slide to 0.1104 with the lower (stepping) slide at zero. The crystal was then rotated until the monoclinic 400 reflection appeared. At this stage, checks were made with the top/bottom and left/right slits to make sure that the crystal was well centred in the X-ray beam and that the counter apertures were well positioned. Similar checks were made with the crystal rotated about 180° to the monoclinic $\bar{4}00$ reflection.

The final check on crystal orientation was to locate the 008 reflection near 0.3248 on the lower (stepping) slide, with the other slides set at zero. There was some variation in the value of c^* for different crystals, and c^* was often closer to 0.0404 than to 0.0406 r.l.u.

At this stage, the first measurements were made of the intensities of the reflections (monoclinic) 400, 16,0,0 and 008. These reference reflections were remeasured at intervals during the measurement of each triplet of reciprocal-lattice levels as a check on the stability of the whole system and irradiation damage to the crystal. The measurements were manually entered on the diffractometer output tape and monitored by the data-processing program.

In order to set the diffractometer for a particular triplet of levels, we found it convenient to leave the lower slide set for the 008 reflection, to adjust the vertical slide and the tilt angle (μ) for the levels in question, and then to run out along the stepping slide until a suitable high-angle reflection was found. The crystal rotation angle was then optimized for this reflection.

Finally, careful checks were made to ensure that the reflections to be measured fell in the reciprocal-lattice hemisphere with L positive, and that they were indexed in a right-handed axial system. The automatic run was then begun at the 2 Å limit on the stepping (C^*) slide, and all reflections were scanned from $H_{\max}$ to $-H_{\max}$ on the scanning slide. Virtually all reflections within (and in some directions a little beyond) the 2 Å limit were measured in this way in fourteen triplet levels, seven even and seven odd. About 2000 reflections were measured in a typical overnight run, and data collection for each species of crystal took slightly more than two weeks.

The derivative crystals required for these measurements were prepared by the diffusion method described above, and about 20 of them were mounted at the same time at the beginning of the data-collection process to ensure that they were all the same. At the end of a run, careful measurements were made of the peak intensity of the $\bar{4}40$ reflection as the crystal was rotated through steps of 15° about the crystal-mounting axis (φ). These measurements were used during data processing in an improved method of absorption correction devised by North *et al.* (1968).

25.1.3.4.2. *Diffractometer output*

The output from the triple-counter diffractometer again consisted of a plain-language output for immediate checking of the results and output at this stage on eight-hole-punched paper tape for immediate transfer to the computer. An example of this record is shown in Fig. 25.1.3.4.

25.1.3.5. *Data processing*

Although the in-house Elliott 803B computer provided much improved facilities over those previously available, its limited store capacity (4096 words of magnetic core memory, but no magnetic drum, disk, or tape facilities) resulted in data processing being carried out in a series of stages, each of limited complexity. Input and output was by means of eight-hole paper tape, which was used as the medium for intermediate storage. The output tape from each stage was used for input to the next stage, together with appropriate parameters. Manual input was restricted to such parameters as unit-cell dimensions and ordinates of the absorption curves, with all other input being in the form of computer-generated output from a previous stage, starting with the diffractometer output tapes. This approach resulted in a great reduction in manual labour and intervention compared with the low-resolution work on lysozyme and the high-resolution stage of myoglobin, and it was probably the first crystal-structure determination that was fully computerized.

As for the initial low-resolution work, the first stage of data processing was input and checking of the diffractometer output, with the programs modified appropriately to deal with the sets of three reflections measured simultaneously. The background-corrected intensities were then output together with a table of the reference reflections used to estimate the extent of any radiation damage. Corrections were then applied for radiation damage if required, followed by application of Lorentz–polarization corrections, followed by absorption corrections.

25.1.3.5.1. Absorption corrections

Although absorption of X-rays by protein crystals is low compared with crystals having a preponderance of heavier atoms, corrections for absorption are required in order to give F values that are sufficiently precise for calculation of the relatively small changes due to the introduction of heavy atoms or anomalous dispersion. The mounting of protein crystals within a glass capillary, normally with a small amount of mother liquor between the crystal and the capillary wall, presents a complicated situation for absorption calculations. Although Wells (1960) wrote a computer program to deal with the situation, a severe impediment to the use of theoretical methods of correcting for absorption results from the very great difficulty in obtaining precise measurements of the mounted crystal, the liquid meniscus and the capillary-tube walls. An alternative approach was to use a semi-empirical method and, for low-resolution lysozyme studies, Furnas' (1957) method had been employed, as described above.

Despite the fact that the method of Furnas had been successful in improving the agreement between symmetry-related reflections in the earlier studies, the implicit assumption that the absorption depended upon the mean direction of the incident and reflected X-ray beams became clearly less valid as the Bragg angle increased. We therefore implemented a development of the method in which the absorption correction applied to any reflection was given by the mean of the two values for the directions of the incident and reflected beams (North *et al.*, 1968).

Although the method was easy to apply and was of significant value, as judged by the improved agreement between symmetry-related reflections, it nevertheless provided only a partial correction for absorption, because of the assumption that absorption is dependent solely on the directions of the incident and reflected beams. The limitations of this assumption are particularly important where precise values are required for Friedel pairs of reflections in order to make use of anomalous-scattering differences in phase determination. Fig. 25.1.3.5 shows two contrasting situations that can arise when the environment of a crystal is asymmetrical because of its mounting. The Friedel pair of reflections shown in Fig. 25.1.3.5(*a*) would suffer similar absorptions, whereas the pair shown in Fig. 25.1.3.5(*b*) would have significant differences because of the location of the mother liquor. In the 2 Å structure determination of lysozyme, an approximate correction was made for this effect. From Fig. 25.1.3.5, it is clear that the absorption error arising from the asymmetric distribution of the mother liquor is 0 for reflections with $h = 0$ and becomes increasingly great as h increases. The assumption was made, therefore, that the required correction was a function only of h and the reflections hkL with constant L were divided into groups with constant h and $-h$. The ratios $\sum_k I(h)/\sum_k I(-h)$ were then plotted against h, as shown in Fig. 25.1.3.6.

Such plots were frequently found to be linear, and the corresponding linear correction was then applied to each row on the more highly absorbed side in order to bring its mean intensity up to that of the other. Where the plots were not linear, so that a simple form of correction was not applicable, the entire set of measurements was usually rejected.

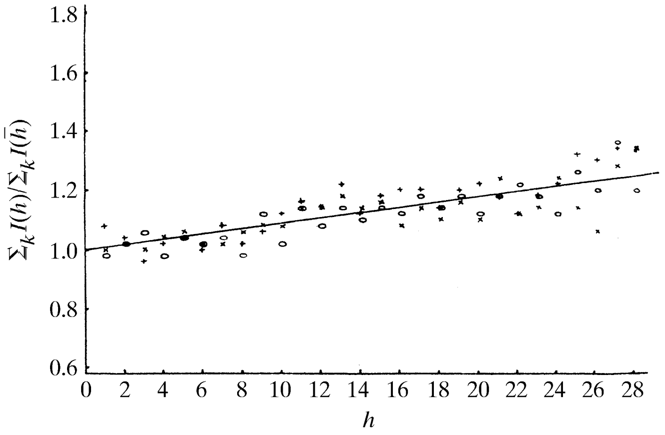

Figure 25.1.3.6
Plot of the ratio $\sum_h I(h)/\sum_h I(-h)$ against h. In this example, a linear correction may be safely applied to equalize the average intensities in opposite rows (North *et al.*, 1968).

25.1.3.6. Further stages of data processing

Many of the programs for subsequent stages of data processing were written by VRS, who had discussed the work with DCP at a meeting in Madras in January 1963 and who joined the team in October 1963.

As described in Section 25.1.3.2, the native data comprised three sets, one of six reciprocal-lattice levels measured from crystals rotated about the *a* axis, and the other two comprising the odd and even subsets of levels collected about the $[\bar{1}11]$ axes. Within these three sets, the odd and even $[\bar{1}11]$ levels had no rows in common with one another, but each had rows in common with the *a*-axis data. Extraction of the related rows permitted the calculation of scale factors by the method of Hamilton, Rollett & Sparks (Hamilton *et al.*, 1965). Application of these scale factors produced a complete set of self-consistent native data.

The derivative data, which consisted of the odd and even levels collected about the $[\bar{1}11]$ crystal axes, were scaled to the native data by the application of two scale factors derived by comparing the totals of the intensities in the odd and even subsets. Because of the high symmetry of the tetragonal space group, up to eight measurements were available for many symmetry-equivalent reflections; for the heavy-atom derivative crystals, these formed four sets of Friedel-related pairs. At this stage, the X-ray amplitude data were on 40 paper tapes for each of the native and three derivative crystals, one for each reciprocal-lattice level. The native and derivative data were then compared level by level, but it was found that the ratio was very nearly a constant, independent of $\sin\theta$. A further numerical factor was applied to all data to bring them approximately to an absolute scale. In the final stage of data processing, the data from the native and the three derivative sets were brought together into a single list containing the native *F*'s and the Friedel pairs for each of the three derivatives. In addition, all of the centric reflections were extracted in order to provide the data for refinement of the heavy-atom parameters.

At this late stage in the data processing, we noticed that some levels agreed significantly less well than the norm with intersecting levels. On 23 October 1963, we had to recognize that the high-resolution measurements had been made from two different types of crystals with essentially identical unit-cell dimensions, but with subtly different diffraction patterns. We designated these two crystal types type I and type II, and set about the task of producing sets of data of one type to use in the structure analysis.

25.1.3.7. The crystal-type problem

This discovery was particularly galling because, although at the time variations in diffraction patterns had been reported for some protein crystals, we had failed to notice that this phenomenon had been mentioned years earlier in a study of lysozyme (Corey *et al.*, 1952).

A preliminary analysis of the differences in the diffraction patterns suggested two important characteristics:

(1) the differences tended to increase with resolution and
(2) the differences appeared to be more consistent with two discrete diffraction patterns than a continuum of patterns lying between two extremes.

The two diffraction patterns were characterized operationally by specific patterns of intensities in the 3–4 Å resolution range (where the differences appeared to be maximal), and particularly by a few adjacent pairs of reflections whose relative intensities interchanged in the two types. The principal diagnostic reflections were 11,11,4 and 11,11,5. In data associated with crystal type I, $I(11,11,4) > I(11,11,5)$, while in crystal type II, $I(11,11,4) < I(11,11,5)$. The 11,11,*L* rows of reflections from the two types of crystals had the structure amplitudes shown in Table 25.1.3.1.

Table 25.1.3.1

Structure amplitudes of the 11,11,*L* reflections from crystal types I and II

Crystal type	Reflection					
	11,11,0	11,11,1	11,11,2	11,11,3	11,11,4	11,11,5
I	29.2	21.8	10.6	18.2	23.1	17.0
II	36.9	25.7	19.7	27.7	26.4	36.8

In order to stand any chance of successfully calculating the lysozyme map by isomorphous replacement, we had to sort all the data so far collected, both native and derivative, into the two types and then recollect 'rogue' data sets in order to assemble complete data sets of one particular type. The alternative was to recollect the whole data on a sounder basis, which we were loath to do, especially as other teams seemed likely to be well advanced in their solution of the lysozyme structure.

It appeared that the bulk of the data that had already been collected using the diffractometer was what we had called type II. We also observed that nearly all the photographic data collected in the heavy-atom proving stage was of type I. This observation was of great importance because it gave us a sound basis for defining the differences between the type I and II diffraction patterns, and it also provided a vital clue in identifying from their shapes the crystals that gave the two types of diffraction pattern. This was very important to us in the selection of crystals to replace the rogue data sets. The crystals that gave the best results for the photographic work tended to be relatively small and flattened along the tetragonal fourfold axis direction, while those that gave the best diffractometer data were the larger isometric crystals, which were more extended along the crystal fourfold axis (Fig. 25.1.2.1). These crystals could be definitely associated with the type I and type II diffraction patterns, respectively. Batches of lysozyme crystals grown according to the procedures defined earlier usually contained both types of crystal. This suggested that the two crystal forms might have originated when the pH of crystallization was on the borderline between two crystal forms of lysozyme. This hypothesis was supported by the observation that crystals grown at a somewhat higher pH had diffraction patterns closely similar if not identical to type I.

The more thorough analysis of the differences between the diffraction patterns for types I and II that these findings permitted showed that the differences in the intensities of equivalent reflections were resolution-dependent. They were very small in the 6 Å region (which probably accounts for the differences not being observed earlier), increased to a maximum at the position of the normal 4 Å peak in the protein diffraction pattern, and fell off at higher resolutions. This pattern is consistent with a lack of isomorphism between the two types of crystal of the kind that may be caused by a slightly different orientation of the lysozyme molecule in the unit cells of the two crystals (Crick & Magdoff, 1956). Such effects may be brought about, for example, by slightly different charge distributions in the protein molecules, rather than by the presence of additional diffracting material in one crystal type or the other. [This conclusion was later confirmed by a detailed analysis of the two structures by Helen Handoll (1985).]

These observations suggested it was safe to go ahead with trying to determine the structure of lysozyme in either type of crystal, and the decision to proceed with the type II crystals was solely on the basis that the bulk of the data already collected were of this type. Knowing the characteristic pairs of reflections that distinguished the two crystal types, we found it relatively straightforward to ascribe each data set to a particular crystal type, even for the heavy-atom derivatives, because the type differences were much larger than the heavy-atom changes at

Table 25.1.3.2
Heavy-atom parameters for the 2 Å structure

O is the occupancy of the heavy-atom site (electrons); B is the isotropic temperature-factor constant; E is the root-mean-square difference between observed and calculated heavy-atom differences for centric reflections (electrons); N is the number of centric reflections in the range $0.01 < \sin^2\theta < 0.15$ used in the refinement and R is the reliability index for observed and calculated heavy-atom changes of centric reflections.

Derivative	Site	x	y	z	O	B (Å^2)	E	N	R
MHTS	I	0.2068	0.6138	0.0507	39.2	17.8	58	1247	0.60
	II	0.2415	0.6393	0.9326	8.8	14.9			
UF	I	0.1783	0.5849	0.7204	55.5	21.0	74	1277	0.52
	II	0.0974	0.8976	0.4650	29.3	24.3			
UN	I	0.0961	0.8938	0.2664	47.1	19.2	80	1140	0.57
	II	0.1898	0.5901	0.7168	42.1	124.8			
	III	0.0446	0.7266	0.5150	9.0	190.2			
	IV	0.0869	0.8976	0.4866	11.4	68.4			
	V	0.2024	0.6388	0.6781	28.6	42.8			

approximately 4 Å resolution. All triplet levels of data that belonged to the type I diffraction pattern were extracted from the total data sets and replaced by equivalent data sets recollected from confirmed type II crystals. This process, whose success was carefully tested and confirmed during the data processing and reduction stage, resulted in consistent data sets at 2 Å resolution for the native lysozyme and all three isomorphous derivatives that were derived from type II crystals.

25.1.3.8. *Final refinement of heavy-atom parameters*

At this stage, we were able to review the refinement of the heavy-atom parameters in relation to the type II crystal data that were now available. Prompted in part by the observation that the heavy-atom positions in myoglobin appeared in regions of high negative density in the final electron-density map, we considered the need to adopt an improved way of modelling the heavy atoms, particularly for the complex uranium compounds, in which the uranium atoms were coordinated to several oxygen or nitrogen atoms. Calculation of the R factors and occupancies of the heavy atoms as a function of $\sin\theta$ showed that the heavy-atom compounds, particularly the uranyl complexes, could not be modelled well by a single atom, but that it was necessary to take into account both the O and the N atoms in the complex and the water that had been displaced by the heavy-atom cluster. The difference electron-density maps did not show the orientation of the O and N atoms, and our first thought was to model the complex in terms of a central U atom, surrounded by a spherical shell of electron density representing the O and N atoms minus a sphere of electron density representing the displaced water. Trial calculations suggested that this model would give improved agreement between observed and calculated $|\Delta F|$ values, most significantly for the uranyl derivatives. On second thought, it occurred to us that a more satisfactory approach might be to derive empirical scattering-factor curves by fitting the curves representing the variation of heavy-atom occupancies with $\sin\theta$ to polynomial functions of $\sin^2\theta$. This was easily accomplished by the use of a standard curve-fitting program and, for ease of use in the phase program, these scattering curves were fitted to curves of the type $f(H) = a + b\sin^2\theta + c\sin^3\theta + d\sin^4\theta$. With this modification, *Pangloss* was used with the type II crystal centric data to obtain the heavy-atom parameters shown in Table 25.1.3.2.

The temperature factors shown in Table 25.1.3.2 most deserve comment. All those obtained for the significant sites (of which there are no more than two for any derivative) are comparable with the overall value for the protein crystals themselves. The very large values obtained for other sites show that these sites are of little importance at high angles and may not represent real sites of heavy-atom attachment. The minor site of MHTS is clearly the SO_3^- group of this molecule (see Section 25.1.3.1).

25.1.3.9. *Calculation of phase values*

Blow (1958), in his determination of the phase angles of the noncentrosymmetric [100] zone of horse haemoglobin, and, later, Cullis *et al.* (1961, 1962), in their determination of the three-dimensional structure of horse haemoglobin, used anomalous-scattering data to supplement the information available from the isomorphous-replacement differences. In each of these studies, phase determination had been carried out by constructing probability curves from the multiple-isomorphous-replacement data and, when the most probable phase angle had been deduced, the anomalous-scattering data were examined. For many reflections, they allowed a choice to be made between two apparently equally probable values of phase angle given by the isomorphous data. This procedure was clearly rather arbitrary and subjective, and a method of combining anomalous scattering with isomorphous replacement in a more rigorous way was described by Blow & Rossmann (1961). In their method, which was subsequently employed for the low-resolution work on lysozyme, use was made of the fact that the mirror image of the Argand diagram for a $\bar{h}\bar{k}\bar{l}$ reflection is similar to the Argand diagram for the hkl reflection, but for the reversal of the sense of the imaginary part of the heavy-atom contribution. The data for the $\bar{h}\bar{k}\bar{l}$ reflections may therefore be treated as though they came from a separate isomorphous compound, with parameters identical to those of the original compound, but with the opposite sign for the imaginary component of the atomic scattering factor.

In the low-resolution lysozyme phase determination (Section 25.1.2.7), intensities of the Friedel pairs of reflections were measured for each of the three heavy-atom compounds, and the problem was treated as if there had been a total of six heavy-atom compounds. Although the method had been found helpful to some extent, analysis of the phases showed that the anomalous-scattering data had played comparatively little part in determining the positions of the centroids of the phase probability distributions, even for reflections with apparently significant anomalous differences.

ACTN observed that this apparent contradiction is because of the fact that the anomalous differences between Bijvoet pairs of reflections measured from the same crystal are inherently more accurate than the isomorphous differences that are measured from different crystals and subject to different systematic errors (North, 1965; Phillips, 1966). Indeed, analysis of the equivalent reflections from native and derivative crystals (Section 25.1.3.6)

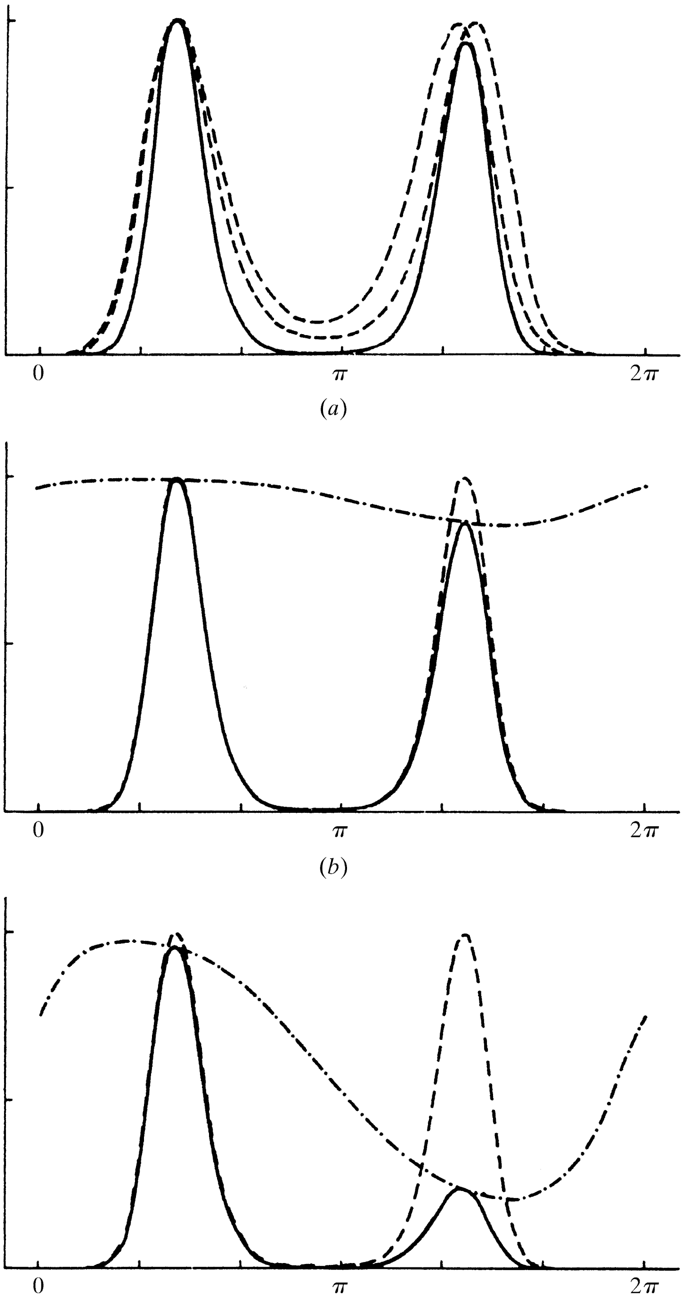

Figure 25.1.3.7
(*a*) Phase probability curve for a Bijvoet pair of reflections (broken lines) with the joint probability curve (full line) derived by the method of Blow & Rossmann (1961). (*b*) Isomorphous-replacement phase probability curve derived from the mean of F_{PH^+} and F_{PH^-} (broken line); anomalous-scattering probability curve (chain line); and joint probability curve (full line) derived by the method of North (1965), using E'(anomalous) = E(isomorphous). (*c*) As (*b*), but with $E' = (1/3)E$. Reproduced with permission from North (1965).

showed that the r.m.s. error E', corresponding to the anomalous differences, was about one-third of E, the error in the isomorphous differences. The result of incorporating this distinction in the phase program is illustrated in Fig. 25.1.3.7. Phase calculations for the new 6 Å and 2 Å maps of lysozyme were therefore carried out by using ACTN's method, with E' set at one third of E.

The data tapes containing the F values for the native and the Friedel pairs of F values for the three derivatives were used as input to a phase program written by ACTN. For acentric reflections, phase probabilities were calculated as described in the previous section, and the centroids of the distributions were determined in order to derive a 'figure of merit', which was applied to the structure amplitudes, as first proposed by Blow & Crick (1959), so as to produce a 'best' Fourier map. For the quite high proportion of centric reflections in the lysozyme diffraction pattern, phase probabilities were calculated by the formula appropriate to the case in which the native and derivative F's are collinear with each other and with the vector due to the heavy atom.

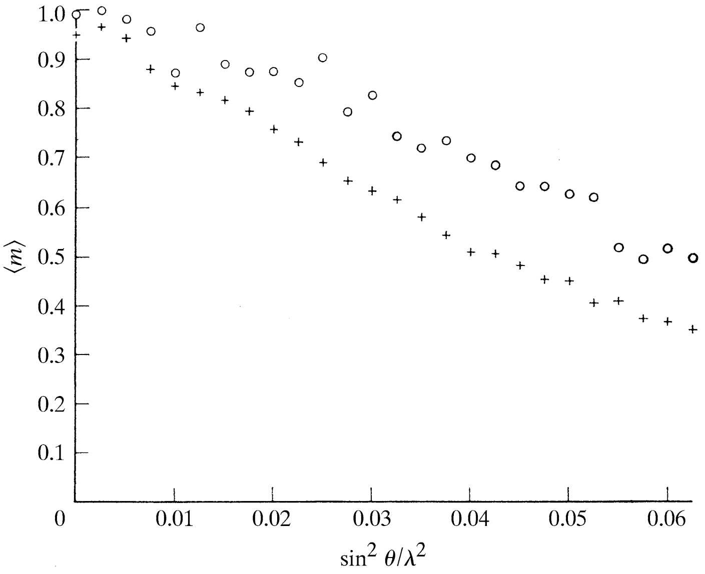

Figure 25.1.3.8
Variation of the mean figure of $\langle m \rangle$ with $\sin^2 \theta/\lambda^2$ (crosses represent acentric reflections, open circles represent centric reflections).

The phases of the 9040 reflections were calculated on the Elliott 803B computer and had a mean figure of merit of 0.60. The variation with angle was very similar to that obtained with sperm-whale myoglobin and is shown for the centric and acentric reflections separately in Fig. 25.1.3.8.

25.1.3.10. The electron-density map at 2 Å resolution

GAM joined the team in early 1964 with the specific task of writing a program for calculating the 2 Å electron-density map. Fortunately, at this stage, the University of London Computing Centre was in the course of acquiring a Ferranti ATLAS computer, which was then one of the most powerful computers available for this kind of work, and GAM eagerly set about taking advantage of its power. Whereas we ourselves had operated the previous MERCURY computer at night, there were machine operators for the ATLAS with whom we left our input tapes; these were very large reels of paper tape comprising all of the amplitude and phase data for the 2 Å set. Following two or three unsuccessful attempts to load the whole of the data without tearing the tapes, GAM modified his program so that the data could be loaded in several sections, which was achieved satisfactorily.

The electron density was calculated at 1/120ths of the cell edge along *a* and *b*, and 1/60ths along *c*. The output from the computer was on punched paper tape, arranged with appropriate insertions of carriage returns and line feeds so that the teleprinter output was in a form suitable for immediate contouring to a scale of 0.75 inches equal to 1 Å. Each *x*, *y* section of the map was printed out in five strips, which had to be glued together to cover the whole area. The contours were drawn initially in pencil on these paper sheets and were then copied in drawing ink to thin Mylar sheets, which were supported for interpretation on Perspex sheets that were stacked and bolted together, with spacers of appropriate dimensions to maintain the scale in the *c* direction, in groups of five for ease of handling. The whole map was drawn on 60 sections perpendicular to the *z* axis, and the bolts holding the blocks of five sheets together were designed to fit into one another to keep successive blocks in register. The maps were viewed on large light boxes, specially constructed for the purpose, though they were not transparent enough for more than fifteen sheets, three blocks of five, to be studied in detail at one time. The contours were drawn on Mylar sheets to avoid waste of the more expensive Perspex that would have arisen from errors. A grid was drawn on a Mylar sheet, which could be superimposed on the contour stacks and used to read the atomic coordinates directly in ångstroms.

The electron density had been calculated using a scale factor such that it was convenient to draw contours at intervals of 0.25 e Å^{-3}; as no $F(000)$ term had been included in the calculation, electron-density values were relative to the mean value for the unit cell. Contours were drawn only for electron densities above the mean, the two lowest levels being drawn in orange ink, and the higher ones in black ink. This proved to be a satisfactory form of representation, as it very clearly revealed regions of continuous high electron density while also showing the positions of significant features of lower density. All the members of the lysozyme group participated in drawing the maps.

To illustrate the result that was obtained, sections $z = 35/60$ to 44/60 of the electron-density map are shown in Fig. 25.1.3.9.

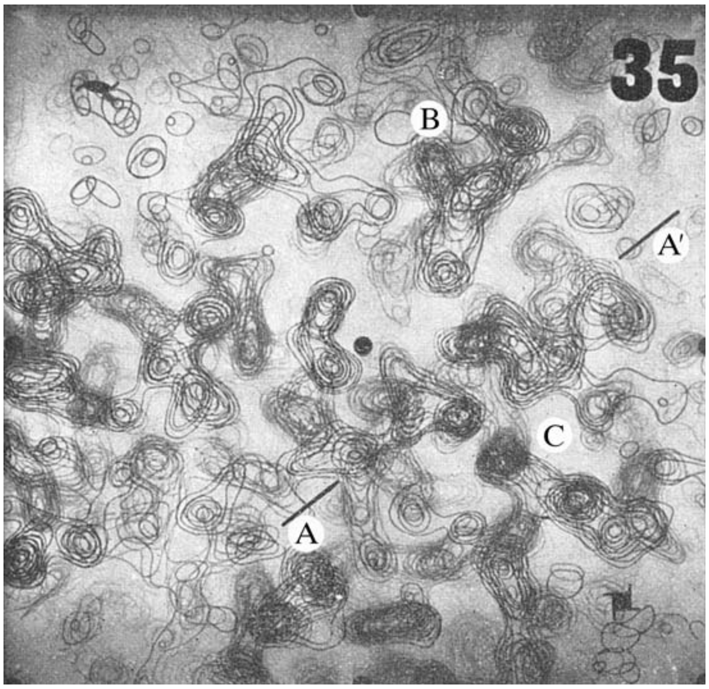

Figure 25.1.3.9
Photograph of sections $z = 35/60$ to 44/60 of the three-dimensional electron-density map of hen egg-white lysozyme at 2 Å resolution. AA′ shows the axis of a length of α-helix lying in the plane of the sections. B indicates an α-helix more nearly normal to the sections. C indicates the disulfide bridge between residues 30 and 115, the sulfur atoms of which lie one above the other. The side chain of a phenylalanine residue is located four residues along the helix from the disulfide, towards the lower sections. Reproduced with permission from *Nature* (Blake *et al.*, 1965). The amino-acid sequence of hen egg-white lysozyme (Canfield & Liu, 1965).

25.1.3.11. Map interpretation and model building

We were fortunate that by the time the map was ready for interpretation, two independent groups of protein chemists, led by Pierre Jollès in Paris and R. E. Canfield in New York, had studied the amino-acid sequence of hen egg-white lysozyme in detail and published their results. Two slightly different amino-acid sequences, complete with the arrangement of the four disulfide bonds, were published by Jollès *et al.* (1964) and by Canfield & Liu (1965), and this information was used intensively in the interpretation of the electron-density map of the protein. The sequence published by Canfield & Liu (1965) is shown in Fig. 25.1.3.10.

Many features were immediately identifiable in the map. These included the side chains of many of the amino-acid residues, especially the disulfide bridges and the aromatic side chains of tryptophan, tyrosine and phenylalanine. Nevertheless, no attempt was made to interpret the map in detail without recourse to the amino-acid sequence. Interpretation began in the part of the map shown in Fig. 25.1.3.9. The strongest feature in this part of the map corresponded to a disulfide bridge (C), in which the two sulfur atoms lie one above the other in the direction of the *c* axis. The first challenge was to identify this bridge. It is clearly connected to a helical region of the molecule (A), which ran in the direction from top right to bottom left of the diagram, with the main-chain carbonyl groups pointing in this direction. Consequently, this helix ran from its amino terminus on the right to its carboxyl terminus in the centre of the map. The map was quite clear enough to count the α-carbons from the cysteine residue that forms part of the disulfide bridge, and it was immediately apparent that the fourth residue from the cysteine towards the carboxyl terminus is an aromatic residue, probably phenylalanine. Inspection of the amino-acid sequence in Fig. 25.1.3.10 showed that only one pair of residues satisfied this condition, Cys30 and Phe34.

Given this start, interpretation of the map and the construction of a molecular model were relatively straightforward. The model was constructed in a metal frame, the top and bottom of which consisted of sheets of blockboard. The *a* and *b* axes were drawn parallel to the diagonals of these boards to cover the coordinate ranges, respectively, $x = -1/4$ to $+1/4$ and $y = 0$ to $+1/2$ to a scale of 2 cm to 1 Å. This was the scale of the brass models, constructed by Cambridge Repetition Engineers Ltd, which were used to build the model. The height of the frame covered the full extent of the *c* axis. The heavy-atom coordinates and the computer programs were both based on the wrong-handed space group $P4_12_12$. It was not until the anomalous scattering from the heavy atoms was incorporated that the correct space group $P4_32_12$ was

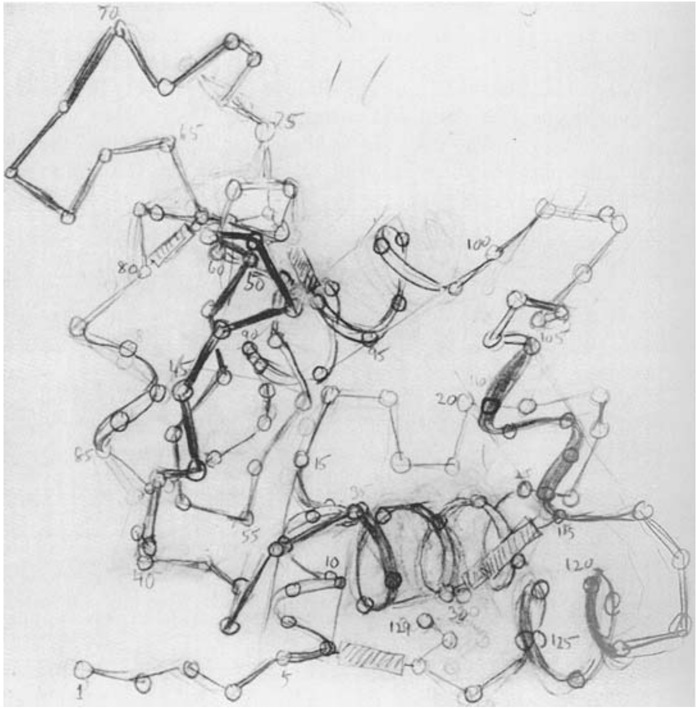

Figure 25.1.3.11
Schematic drawing of the main-chain conformation of lysozyme. The drawing was made from observations of the molecular model by Sir Lawrence Bragg and later prepared for publication by Mrs S. J. Cole.

Table 25.1.3.3
Discrepancies in amino-acid sequences (excluding Asp/Asn)

	Residue						
Reference	40	41	42	58	59	92	93
Canfield & Liu (1965)	Thr	Gln	Ala	Ile	Asn	Val	Asn
Jollès *et al.* (1964)	Gln	Ala	Thr	Asn	Ile	Asn	Val

assigned. The Fourier-map sheets were actually stacked the opposite way round and a left-handed system of axes was used for the model. In retrospect, this should have been put right at once, but the system was not easy to change.

Holes were drilled in the top and the base boards on the grid defined by the *a* and *b* axes, and these were used to support an array of brass rods parallel to the *c* axis to which the model components could be attached. The model building was carried out by two subgroups, CCFB and VRS in one and ACTN and DCP in the other, so that work could go on continuously throughout each day. The method employed was to examine the map density corresponding to the next amino-acid residue to be located and to mark the positions of the constituent atoms with small washers or nuts. The coordinates of these atoms were then read from the map (making use of the superimposed grid and estimating the *z* coordinates from the extent to which adjacent *z* sections contributed to the density). These coordinates were then located in the model by means of the coordinate grids drawn on the base and top boards and by the use of a plumb line marked with the *z* coordinates. At this stage it was usually possible to fix a model of the amino-acid residue in place in the model frame with remarkably little trouble, though, of course, fine adjustment was necessary as the model grew.

This bout of model building began towards the end of February 1965 and proceeded quite rapidly. The main difficulties arose from the fact that the two amino-acid sequences that were available did not agree in every respect. Eleven amino-acid residues were identified differently by Jollès (Jollès *et al.*, 1964) and by Canfield (Canfield & Liu, 1965). Four of the discrepancies involved Asn and Asp, which cannot be distinguished in the electron-density map with any degree of certainty. The remaining discrepancies are shown in Table 25.1.3.3.

Inspection of the residues 40, 41, 42, 92 and 93 showed quite clearly that the shapes in the electron-density map fitted the Canfield side chains. Our initial conclusion, however, was that the electron densities corresponding to residues 58 and 59 were more consistent with the sequence proposed by Jollès than that published by Canfield. Accordingly, in our first detailed description of the structure (Blake *et al.*, 1965), we accepted the identification of these residues by Jollès and his colleagues. As will be seen, this was a mistake.

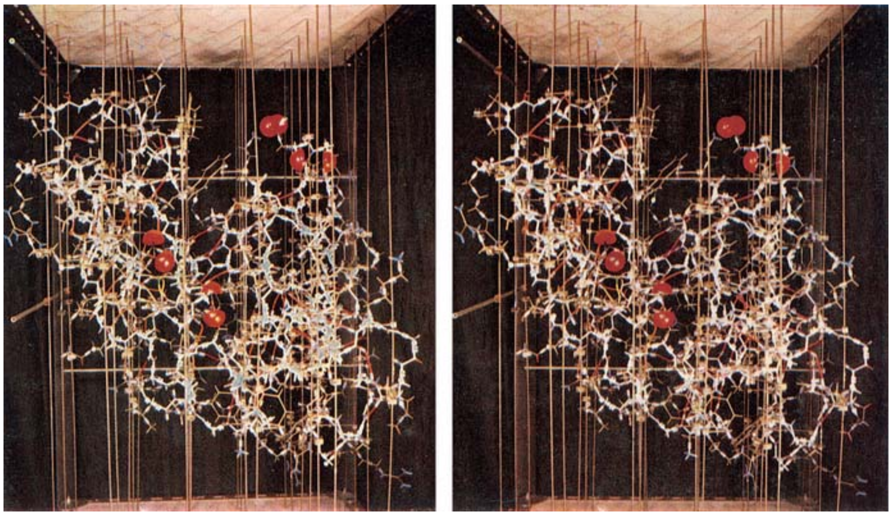

Figure 25.1.3.12
Stereo-photographs of a model of the lysozyme molecule to a scale of 2 cm to 1 Å. The main polypeptide chain is painted white, and nitrogen, oxygen and sulfur atoms are indicated by blue, red and green sleeving, respectively. Some hydrogen bonds are shown by red connections. Oxygen atoms of the acid side chains near the cleft, Glu 35, Asp 52, Asp 101 and Asp103, are shown by red hemispheres (Blake *et al.*, 1967).

The model was completed in time for it to form the centrepiece at Bragg's 75th birthday party at the Royal Institution on 31 March 1965, and a description was submitted to *Nature* at about the same time (Blake *et al.*, 1965). One of the difficulties at this stage of development of the subject was that computer graphics had not yet been developed to the stage at which illustrations of protein structures could be produced with any degree of facility. Consequently, we were most grateful that Sir Lawrence Bragg enthusiastically drew the model freehand. His drawing provided the main illustration for the published paper: the original sketch is reproduced in Fig. 25.1.3.11.

During the early summer of 1965, we rebuilt the model, taking care to ensure that the components fitted the electron density as well as could be judged by eye, and that the contacts between them were fully consistent with current understanding of van der Waals forces and hydrogen bonds. The model components were fixed firmly in position with small brass clamps, designed and constructed by Bruce

Morris in the Royal Institution workshop, so that at the end of the process we had an unrealistically rigid model that incorporated all the information available to us at the time. At this stage it became clear that the Canfield sequence (Fig. 25.1.3.10) was to be preferred in every respect.

A stereo-photograph of this model (Blake *et al.*, 1967) is shown in Fig. 25.1.3.12 in a view that shows the most striking feature of the molecule. The molecular face in the foreground of this view is crossed by a deep cleft, roughly parallel to the *c* axis of the crystal unit cell.

25.1.4. Structural studies on the biological function of lysozyme

25.1.4.1. Lysozyme substrates

By the summer of 1964, the results for the structure determination of lysozyme were sufficiently promising for us to consider diffraction studies on the biological function of lysozyme. At about the same time, the Royal Society invited Max Perutz to organise a Discussion Meeting on lysozyme at The Royal Institution in early 1966, to which the leading workers worldwide would be invited. This provided an additional spur to our efforts.

Simultaneously with his discovery of lysozyme in 1922, Fleming had found a gram-positive species of bacteria, *Micrococcus lysodeikticus*, that was particularly susceptible to lysis by lysozyme (Fleming, 1922). During the 1940s and 1950s, further work by a number of authors had shown that lysozyme exerted its biological effects through hydrolysis of the bacterial cell wall. These studies led to a definitive description of the polysaccharide component of the bacterial cell wall, as shown in Fig. 25.1.4.1.

The structure is composed of alternating sugars, linked by $\beta(1 \rightarrow 4)$ glycosidic links, of *N*-acetylglucosamine (GlcNAc, abbreviated by us at the time as NAG) and *N*-acetylmuramic acid (MurNAc, previously abbreviated as NAM). The 3-hydroxyls of the MurNAc residues are attached to short peptides, and the peptides themselves are cross-linked to provide an extensive and rigid two-dimensional proteoglycan network. Lysozyme cleaves the $\beta(1 \rightarrow 4)$ glycosidic bonds between MurNAc and GlcNAc residues, thus leading to the dissolution of the bacterial coat and lysis of the bacterium.

Kinetic studies on the activity of lysozyme were hampered by the lack of a suitable small-molecular-weight substrate. The turbidometric assay in use at the time, and still in use today, followed the change in optical density of a suspension of *Micrococcus lysodeikticus* cells as the cells were lysed by lysozyme. The assay could work reliably but it was sensitive to physical parameters such as ionic strength, the method by which the cells were suspended and product inhibition. In 1962, Wenzel *et al.*, in an effort to obtain a small-molecular-weight substrate, had reported that lysozyme promoted the cleavage of the trimer of GlcNAc, tri-*N*-acetylchitotriose, releasing dimer and monomer sugars, and that the monomer, GlcNAc, was an inhibitor of lysozyme (Wenzel *et al.*, 1962). Compounds such as glucose or cellobiose that lacked the *N*-acetyl group did not inhibit.

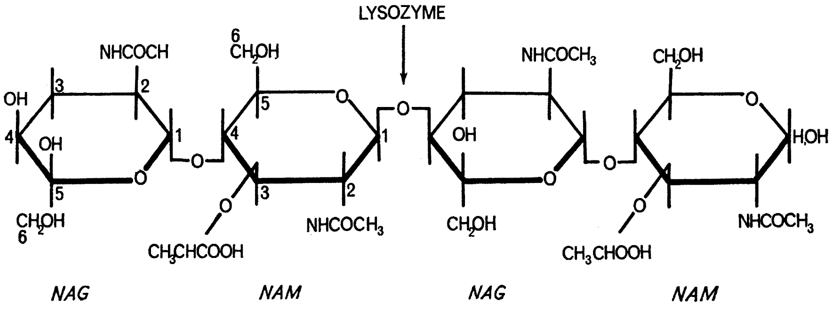

Figure 25.1.4.1
The cell-wall tetrasaccharide with the $\beta(1 \rightarrow 4)$ glycosidic bond that is hydrolysed by lysozyme indicated (Blake *et al.*, 1967).

John Rupley extended this work. Rupley, a chemist from the University of Arizona, Tucson, played a crucial role in developing the mechanisms for lysozyme catalysis. In results that were summarized in 1964 and 1967 (Rupley, 1964, 1967) and made available to workers at the Royal Institution in 1965, he showed that the rate of hydrolysis of GlcNAc homopolymers increased by 30 000 as the chain length increased from trimer to hexamer, and that there was no further increase in rate for substrates of greater length than the hexamer. Furthermore, the cleavage patterns for the smaller polymers were complex, but the optimal substrate, the hexamer, was cleaved to a tetrasaccharide and a disaccharide.

Thus by the time we began structural studies, the nature of the substrate and the specificity of lysozyme were established. GlcNAc was the only compound that was available commercially. This seemed a good starting point. It was anticipated that as a competitive inhibitor it would bind to and allow the identification of the catalytic site.

25.1.4.2. The crystal structure of GlcNAc

During the first two years of her graduate work (1962–1964), LNJ determined the crystal structure of GlcNAc. β-D-*N*-Acetylglucosamine was crystallized from a methanol–water mixture, and diffraction data were recorded on film with a modified Weissenberg camera. Intensities were estimated visually from comparison with a scale of fixed-time exposures of the attenuated main beam. The structure was solved manually using a sharpened Patterson function and application of the minimum function of Buerger (1959). The structure revealed a standard glucopyranose ring in the chair conformation with the plane of the *N*-acetyl group normal to the ring (Johnson & Phillips, 1964; Johnson, 1966). The structure of glucosamine hydrochloride had been solved by Cox & Jeffrey in 1939 (Cox & Jeffrey, 1939), a remarkable early achievement.

By 1963, about ten glucopyranose structures were available, including that of cellobiose (Jacobson *et al.*, 1961). An analysis by Ramachandran *et al.* (1963) showed that the glucopyranose ring is remarkably uniform in its conformation and may be regarded as a rigid structure.

The final difference-Fourier synthesis of β-GlcNAc revealed an additional peak adjacent to the C1 carbon atom in the position of a hydroxyl group in the α configuration. Peak heights suggested that there could be a mixture in the crystal of approximately 80% β-*N*-acetylglucosamine and 20% α-*N*-acetylglucosamine. Refinement indicated that a mixture of the two anomers could be accommodated in the crystal lattice.

Tests on the optical rotation of the crystalline sample after dissolution, compared with the starting material, also added support to the notion that the crystal contained a mixture of α and β anomers, probably as a result of mutarotation during crystallization. Although a later and more precise structure determination of GlcNAc indicated a lower proportion of the α anomer (Mo & Jensen, 1975), mixtures of α and β sugars in crystals have been observed for other compounds (Jeffrey, 1990). The consideration of the α and β anomers of GlcNAc meant that we were keenly aware of the importance of configuration at the C1 atom. This turned out to be essential when we were interpreting the results with lysozyme.

25.1.4.3. Low-resolution binding studies of lysozyme with GlcNAc and other sugars

In the first binding studies of lysozyme with GlcNAc, crystals were soaked overnight in solutions of 0.15 *M* GlcNAc in the standard crystallization medium, and a 15° precession photograph was recorded by LNJ. The changes in intensities of reflections compared to a native lysozyme photograph were extremely small, much smaller than those observed with the heavy-atom derivatives, but were sufficiently promising to encourage us to collect three-dimensional data to 6 Å resolution. Data were collected on the linear diffractometer using the three counters in the flat-cone setting over a period of about 20 h, as described for the heavy-atom derivatives. The data were processed using the programs of ACTN and VRS on the Elliott 803B computer. The 6 Å difference-Fourier map, using the phases from the improved set of heavy-atom derivatives, was obtained at the end of October 1964. It showed a single rather elongated peak which, when superimposed onto the 6 Å model, was located in the cleft in the enzyme surface between the two domains (Johnson & Phillips, 1965).

The power of the difference-Fourier technique in protein crystallography was immediately demonstrated by this first 6 Å electron-density difference map for the lysozyme–inhibitor complex, as had also been demonstrated earlier in the work (Stryer *et al.*, 1964) on the binding of azide to sperm-whale myoglobin. Once a protein structure had been solved, it was apparent that ligand-binding sites could be established with ease. Following the GlcNAc result, 6 Å binding studies were repeated with a number of other compounds (Blake *et al.*, 1967). Kinetic studies using the turbidometric assay were carried out with each of the compounds in order to establish the mode of inhibition of lysozyme activity. We were fortunate in being able to use the skills of JWHO, a carbohydrate chemist who had been at the Royal Institution for many years. JWHO had synthesized 6-iodo-6-deoxy-*N*-acetyl β-methylglucosaminide, a compound which was found to inhibit more powerfully than GlcNAc itself. The low-resolution binding study showed a stronger and more compact peak at the catalytic site than that observed with GlcNAc, but it was not possible to resolve the iodine and hence identify the six positions of the sugar.

By January 1965, we had been given a sample of the disaccharide di-*N*-acetylchitobiose, $(\mathrm{GlcNAc})_2$, sent by John Rupley. Efficiency of data collection and map production had increased. Data collection was started on 19 January and the map was obtained by 28 January. Other results followed with *N*-acetylmuramic acid (a gift from R. W. Jeanloz) and the disaccharide *N*-acetylglucosamine β-(1,4)-*N*-acetylmuramic acid (GlcNAc-MurNAc – a gift from N. Sharon) (Fig. 25.1.4.2).

As part of these studies, penicillin V and *p*-iodophenoxymethyl penicillin potassium salt were also investigated. They were observed to inhibit lysozyme. Crystallographic studies showed that the penicillins did indeed bind to lysozyme in the catalytic cleft, but at a site remote from the GlcNAc binding site (Johnson, 1967). As established shortly after this result was obtained in 1965, penicillin exerts its potent antibiotic activity by inhibition of the enzymes responsible for the biosynthesis of the peptide cross-linking component of the bacterial cell wall (Tipper & Strominger, 1965; Wise & Park, 1965). An original suggestion that penicillin might resemble MurNAc turned out to be incorrect (Collins & Richmond, 1962). The interactions of penicillin with lysozyme are probably fortuitous, but were not fully investigated.

By the end of May 1965, we were ready to move on to 2 Å data collection, a formidable task that required fourteen crystals and more than two weeks continuous data collection on the multiple-counter linear diffractometer. Data for the lysozyme–GlcNAc complex were completed first, and the map was available around October 1965. The electron density was puzzling, and an interpretation was not possible until the high-resolution results with the trisaccharide were available.

25.1.4.4. Binding studies of lysozyme with tri-N-acetyl-chitotriose, $(\mathrm{GlcNAc})_3$, at 2 Å resolution

John Rupley visited the Royal Institution in July 1965. He brought with him a sample of tri-*N*-acetylchitotriose (Fig. 25.1.4.2), previously abbreviated as tri-NAG and now as $(\mathrm{GlcNAc})_3$. The lysozyme–$(\mathrm{GlcNAc})_3$ complex turned out to be the crucial structure for understanding activity. When lysozyme crystals were soaked in 0.05 *M* $(\mathrm{GlcNAc})_3$ solution, they turned opaque and became difficult to mount for X-ray studies. The problem was overcome by soaking the crystals already mounted in a capillary tube. By 17 July 1965, a 6 Å map of the lysozyme–$(\mathrm{GlcNAc})_3$ complex was obtained and showed a peak occupying the whole top part of the cleft on the enzyme surface.

Rupley had also succeeded in co-crystallization of lysozyme with $(\mathrm{GlcNAc})_3$. Data collected from these crystals gave an identical difference-Fourier synthesis to that obtained with crystals soaked in $(\mathrm{GlcNAc})_3$. Data from another co-crystallized crystal, which were collected ten days later, also gave an identical result, indicating that there had been no hydrolysis of the trisaccharide in the crystal during this time. The way was open for high-resolution data collection with $(\mathrm{GlcNAc})_3$. Rupley set up co-crystallizations of lysozyme with $(\mathrm{GlcNAc})_3$ (with concentrations 1:1.1 molar ratio under standard conditions) at the Royal Institution during the hot August of 1965. The crystals grew well and provided us with a plentiful supply of crystals for the 2 Å data collection, which was carried out by LNJ following the same procedures as for the native crystals described above.

The 2 Å difference-electron-density map arrived on Thursday 6 January 1966, but there was a mistake. After correction and the laborious task of contouring by hand and transferring the contours to transparent sheets had been completed, serious model building by DCP, LNJ, ACTN and other members of the team began on 19 January 1966.

The interpretation of the difference map for $(\mathrm{GlcNAc})_3$ was straightforward. Three sugars could readily be identified in the density. The first occupied a site at the centre of the cleft at a position similar to that occupied by GlcNAc by itself and labelled site C. The acetamido group was visible and fitted neatly into a pocket where there were complementary hydrogen bonds between the NH and CO of the acetamido group and the main-chain carbonyl oxygen of residue 107 and the amido group of residue 59. Lysozyme has three tryptophan residues at the catalytic site. One of these, Trp108, was at the bottom of the acetamido pocket and made van der Waals contacts to the methyl group of the acetamido. The precise and extensive contacts to the acetamido group explained immediately the specificity of lysozyme for *N*-acetyl sugars. The free reducing group of the sugar in site C pointed down (towards lower z). The second sugar could be fitted to the density above the first (in the direction of increasing z), linked to the O4 of the sugar in site C. It was clear that a second tryptophan, Trp62, stacked against the glucopyranose ring for this sugar in site B, and that there was a shift of this tryptophan towards the sugar. This and other conformational changes could explain the tendency of the lysozyme crystals to become disordered when soaked in $(\mathrm{GlcNAc})_3$ solutions.

In cellobiose, whose crystal structure had been determined in 1961 by Lipscomb and colleagues (Jacobson *et al.*, 1961), the conformation about the $\beta(1\rightarrow4)$ glycosidic link rotates the second sugar about 180° with respect to the first, and there is an intramolecular hydrogen bond between the O3 hydroxyl of one sugar and the O5 of the adjacent sugar. This relative orientation of the two adjacent sugars was found to fit the density for sugars C and B and also to agree with models proposed by Carlstrom (1962) for chitin and the analysis of Ramachandran *et al.* (1963). The lobes representing the acetamido and C6 alcohol groups for site B provided further confirmation for this orientation. The third sugar in site A appeared less well located, but nevertheless could be placed in density and was observed to make satisfactory contacts with the protein.

The interpretation of the difference-Fourier map was made by one worker without reference to the protein structure, while a second worker fitted the model into the protein structure. It was most exciting and satisfying to observe the contacts when the skeletal models of the sugars were fitted into the skeletal model of the protein. Shifts in atomic coordinates of selected protein groups were estimated from the gradient of electron density in a difference map divided by the curvature of the electron density at that point, as described by Lipson & Cochran (1968). Using this formula, the shift in Trp62 was calculated to be 0.75 Å, a value that turned out to be accurate when the lysozyme–$(\mathrm{GlcNAc})_3$ complex was refined by least-squares methods many years later (Cheetham *et al.*, 1992). It was also noted that there were two acidic residues on either side of the catalytic cleft, Glu35 and Asp52, which were some distance from the $(\mathrm{GlcNAc})_3$ position. There was a further acidic residue, Asp101, near the top of the cleft.

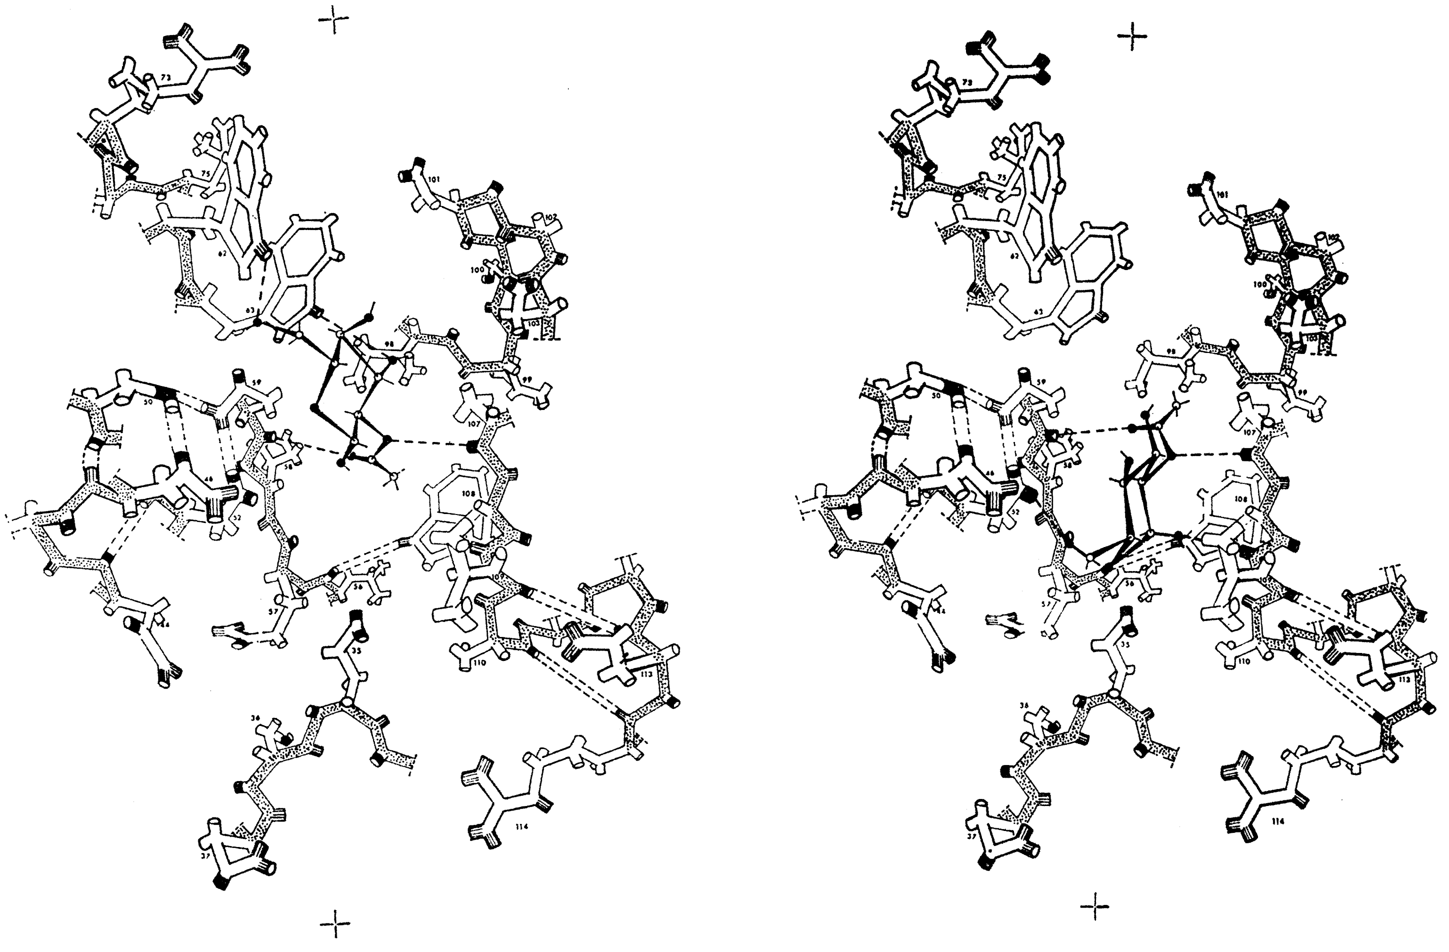
The structure of the $(\mathrm{GlcNAc})_3$–lysozyme complex allowed an interpretation of the GlcNAc result. It was apparent that GlcNAc bound to site C in one or other of two distinct but closely related ways, depending upon whether it is in the α or β enantiomeric form (Fig. 25.1.4.3).

The GlcNAc molecule had evidently undergone mutarotation in solution to produce an equilibrium mixture of α and β forms, both of which bound to lysozyme, although of course the specificity of the enzyme for longer oligosaccharides is for β-linked sugars. Both binding modes exploited the specificity of the *N*-acetyl group and its interactions with the enzyme.

One mode was characteristic of β-GlcNAc, as observed for the terminal sugar of $(\mathrm{GlcNAc})_3$. The other mode was characteristic of α-GlcNAc and involved a rotation about the hydrogen bonds of the acetamido group to the protein. This finding could explain the result for 6-iodo-6-deoxy-*N*-acetyl α-methylglucosaminide, which could not fit into the α-GlcNAc site because of the additional methyl group but could only be accommodated in the 'β-site'. The dual mode of binding for the terminal residue in the α or β configuration could also explain the bifurcated peak observed for the disaccharides GlcNAc-MurNAc and $(\mathrm{GlcNAc})_2$. When the terminal sugar is in the α configuration, the second sugar is placed out of the main run of the cleft, while in the β configuration the second residue is as in site B of the trisaccharide complex.

25.1.4.5. Proposals for the catalytic mechanism of lysozyme

A Royal Society Discussion Meeting had been arranged for 3 February 1966 under the organization of Max Perutz. CAV, from University College, London, who had worked on mechanisms for the non-enzymic hydrolysis of glycosides in solution, had been invited to contribute to this meeting. In mid-January (the exact date is not recorded) he visited the Royal Institution to discuss the possible reaction mechanism of lysozyme in the light of the crystallographic evidence. At that stage, the crystallography had shown, from low-resolution studies, the inhibitor binding sites within a surface cleft lined with several acidic residues that included Glu35 and Asp52. CAV's work had shown that the hydrolysis of methyl-α-D-glucopyranoside proceeded *via* a ring-closed carbonium-ion intermediate (*i.e.* a carbocation) and that the rate-determining step was the heterolysis of the C1 carbon–oxygen bond (reviewed in Vernon, 1967). Rupley's studies with ^{18}O water had shown that hydrolysis of oligosaccharide substrates by lysozyme also proceeded through cleavage of the C1—O bond (Rupley, 1967). Whereas in free solution the carbocation intermediate is presumed to be stabilized by interaction with solvent, in the catalytic site of lysozyme it was suggested that the carbonium-ion intermediate might be stabilized by the nearby ionized carboxylate of one of the acidic residues in the catalytic site.



(*a*) (*b*)

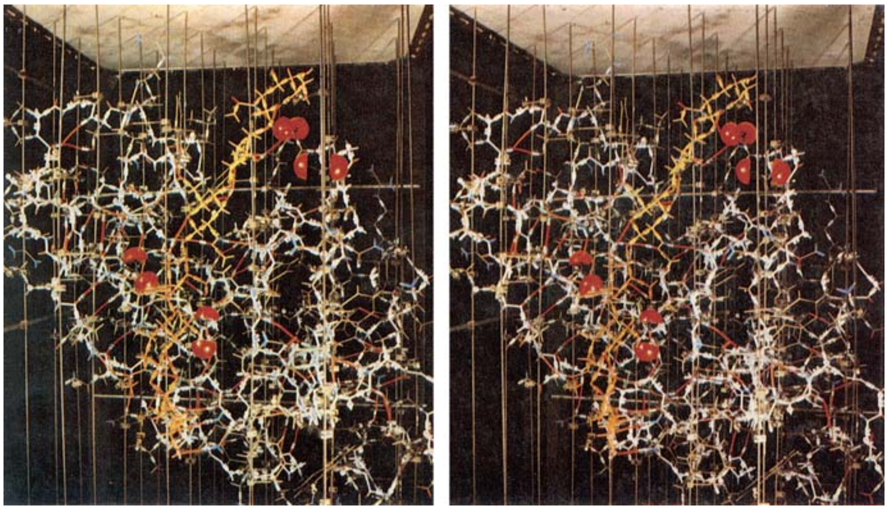

Figure 25.1.4.4
Stereo-photographs of a model of the lysozyme molecule showing how a hexasaccharide substrate may bind to the enzyme. The yellow trisaccharide model shown at the top of the cleft is in the position occupied by tri-*N*-acetylchitotriose in the crystals of its complex with lysozyme. The orange trisaccharide in the lower part of the cleft has been added by model building alone. The fourth sugar residue from the top, the uppermost orange one, is distorted from the chair conformation (Blake *et al.*, 1967). The glycosidic linkage that is broken is the one between the fourth and fifth sugar residues from the top. It lies between the side chains of Glu35 (to the right) and Asp52 (to the left), the oxygen atoms of which are marked by red hemispheres. Asp101 and Asp103, near the top of the cleft, also have their oxygen atoms marked.

The interpretations of the $(\mathrm{GlcNAc})_3$ and the GlcNAc complexes were finished by Monday 31 January 1966. The date is significant. The Royal Society Discussion Meeting had been arranged for the following Thursday. The results with the non-hydrolysable complex with $(\mathrm{GlcNAc})_3$ had identified the catalytic site and had provided immediate explanations for the specificity requirement for the enzyme. However, information on how a true substrate might bind was missing. This problem was solved in one day. DCP, noting that Rupley's work had shown the optimal substrate to be a hexasaccharide, constructed a hexasaccharide substrate in sites A–F, using the position of the experimentally determined trisaccharide in sites A–C and model building those sugars in sites D–F. Noting also the specificity of lysozyme for bacterial-cell-wall substrates, where the polysaccharide is composed of alternating $\beta(1\rightarrow4)$ linked GlcNAc and MurNAc residues, and the bond cleaved is that between MurNAc and GlcNAc residues, but not that between GlcNAc and MurNAc residues, he also examined sites likely to be specific for MurNAc. It was apparent that, for steric reasons, sites A, C and E could not accommodate MurNAc residues, but that sites B, D and F could do so. Thus the site of cleavage must be between sites D and E (or sites A and B, but this could be discarded because the trisaccharide complex was stable).

Close to the bond between sites D and E were two acid residues (Fig. 25.1.4.4). As noted previously by members of the team, one of these, Glu35, was in a non-polar environment and shielded by Trp108, Val109 and Ala110. In this environment, the carboxylic acid was likely to have a raised p*K* and to be protonated at pH 5, the optimal pH for activity against homopolymers of GlcNAc. The other acid group, Asp52, was also buried, but in an environment that was largely polar and at the centre of a hydrogen-bonding network. Hence it might be predicted that its p*K* was likely to be similar to that of a carboxyl group in an aqueous environment, and the group would therefore be mostly ionized at pH 5. There was one other important factor. The sugar in site D could not be accommodated in the usual chair conformation of a glucopyranose ring. In order to avoid overcrowding between the C6O6 atoms of the alcohol group and the protein atoms at site D, it was necessary to distort the sugar ring from the conventional chair conformation to a sofa conformation. This relieved the overcrowding by bringing the C5—C6 bond axial and retained the links from C4—O4 and C1—O4′ equatorial, so that the adjacent sites of C and E were not perturbed by the distortion of the sugar in site D (Fig. 25.1.4.4). CAV visited the Royal Institution on a second occasion between the completion of the model and the Royal Society meeting, probably on 1 February. When shown the hexasaccharide substrate complex with two acid residues on either side of the susceptible bond and the distortion of the sugar in site D, CAV explained that this was exactly what he would expect from his own work for a carbonium-ion mechanism with transition-state distortion of the substrate.

T
Dear David,
I have made all the corrections in the main drawing and have started to paint. I hope to be finished in a month.
Meanwhile I have redrawn the substrate and here is a print of the new drawing, which I will ask you to correct & send back to me.
two minor points in my part: ① This atom was left off in your sketch.
② It would seem to me that (a) & (b) should be parallel, unless you wish this section to be distorted also.
Best regards
Irv

Figure 25.1.4.5
Draft sketch of the lysozyme–hexasaccharide substrate complex prepared by Irving Geis and annotated by David Phillips for an article published in *Scientific American* in 1966 (Phillips, 1966).

The mechanism was presented for the first time at the Royal Society meeting on 3 February 1966. It was noted that the nearest oxygen of the protonated Glu35 was about 3 Å from the glycosidic oxygen between residues D and E (the O1 atom of residue D and the equivalent O4 atom of residue E). On the other side of the cleft, the nearest oxygen of the ionized Asp52 was about 3 Å from the C1 atom of residue D and about the same distance from the O5 of that residue. The distances were, of course, subject to some error from experimental model building. It was suggested (Blake *et al.*, 1967; Phillips, 1967) that:

(1) Asp52 carries a negative charge that promotes the formation of a carbonium ion at C1 of residue D and stabilizes it when formed;
(2) distortion of residue D from the chair conformation into the sofa conformation would contribute to stabilization of a carbonium ion at C1 by favouring a conformation in which the charge at C1 could be shared with the ring oxygen atom (Lemieux & Huber, 1955), and hence

contribute to the consequent weakening of the C1—O1 bond; and

(3) Glu35 could act as a proton donor, facilitating the formation of a hydroxyl group with the bridge oxygen atom (O1), and release of residues E and F.

Fig. 25.1.4.5 shows a sketch of the proposed lysozyme–hexasaccharide substrate complex prepared by Irving Geis for a *Scientific American* article published later that year (Phillips, 1966).

As Perutz commented in his closing remarks at the Royal Society meeting: 'For the first time we have been able to interpret the catalytic activity of an enzyme in stereochemical terms' (Perutz, 1967). The scheme for catalysis has been subjected to numerous experimental tests and has been investigated further in crystallographic experiments. The mechanism provided a satisfactory explanation for the body of evidence already in existence at the time of the proposals and has been substantiated by the results of new experiments designed to test it (see, for example, Imoto *et al.*, 1972; Ford *et al.*, 1974; Strynadka & James, 1991; Hadfield *et al.*, 1994; Jolles, 1996).

This work would not have been possible without the continuous support and encouragement of Sir Lawrence Bragg and the Medical Research Council, UK, for which we were and are most grateful. We are also grateful to our colleagues Robert Canfield, Pierre Jolles, Gordon Lowe, John A. Rupley, Nathan Sharon and others who shared their results on the catalytic mechanism with us before publication. The successful outcome also depended greatly upon the skilled work of the craftsmen in the Royal Institution's mechanical and electronic workshops, Messrs T. H. Faulkner, S. B. Morris, J. E. T. Thirkell and A. R. Knott. Finally, we acknowledge gratefully the unstinting contributions made by our team of research assistants, Mrs W. J. Browne, Mrs A. Hartley, Mrs K. Sarma, Miss D. Glass, Mrs R. Arthanari, Mrs S. J. Cole, Mrs J. A. Conisbee and Miss M. Hibbs. Clearly, thirty years ago protein-structure analysis was still very labour-intensive, despite the advances in computing and diffractometry described above. This was largely because we were still designing and building our own apparatus and drawing maps and building models by hand. This situation has been transformed chiefly by the availability of more powerful computers and X-ray detectors, by the developments of computer graphics, and by the exploitation of synchrotron radiation. The review has used the original figures prepared during the 1960s with a few exceptions. We acknowledge with special thanks the skills of Stephen Lee in scanning and reproducing these figures.
